KING'S COLLEGE HOSPITAL REPORT FOR 1841;

With Remarks.

By WILLIAM AUGUSTUS GUY, M.B. Cantab.

Professor of Forensic Medicine, King's College,
London, and Physician to the King's
College Hospital.

(For the Medical Gazette.)

IN the MEDICAL GAZETTE, Feb. 19th, 1841, an analysis was given of 4250 cases registered in the books of the King's College Hospital during the previous year. The period embraced in that report was less than nine months, as the hospital was not opened for the reception of patients till April 15th, 1840. The present report is for the entire year 1841.

The number of registered cases exceeds 8000, which is probably about 2000 short of the entire number treated at the hospital during 1841, exclusive of casualties; of which number, under a complete system of registration, by far the majority might have been entered upon the books. The cases omitted from the report are almost exclusively in-patients; and of these the larger number are physicians' cases, the urgent cases admitted under the care of the surgeons having been carefully registered during the latter part of the year. Of the medical and surgical out-patients a very small number have been omitted, consisting chiefly of cases about which some doubt existed at the time of their first application, the name of the disease not having been subsequently entered.

The only change in the medical staff during the year 1841, which may have

affected the number and proportion of the patients, is that caused by the appointment of Dr. Arthur Farre to the care of the Diseases of Women and Children.

From what has been stated, it will appear that the report is by no means so complete as might be wished, and that it conveys an imperfect idea of the prevalent diseases of the poorer classes in one of the most crowded parts of the metropolis. The proportionate frequency of those diseases which are not sufficiently severe to be admitted into the wards of an hospital, or which are excluded by the rules of the establishment, is, however, faithfully represented; and, as far as this class of patients is concerned, it is hoped that the report will supply some useful information*.

Analysis of 8029 Registered Cases of Disease, treated at the King's College Hospital, during the year 1841.

Pertussis . . .	28	35	63

* I am happy to state that an efficient plan for registering the in-patients of the hospital has just been adopted; so that there is every reason to expect a more full report for the present year, and a complete account of all the cases treated at the hospital during the year 1843. I may mention, also, that a sub-committee of the Statistical Society has been formed, for the purpose of promoting an improved and uniform system of registration in the hospitals of London; and that their proposals have been favourably received, and their objects promoted, by the medical officers of many of those institutions.

REMARKS.

Catarrhus Epidemicus, Influenza.—

This disease was extremely prevalent during the months of February, March, and April. Extreme debility, accompanied in most cases by languor and mental depression, was superadded to the ordinary symptoms of catarrh, and in many instances, more especially in aged persons, this symptom of debility was the only one present. In a few cases a papular eruption appeared on the skin, and minute ulcers formed, which healed with difficulty. In addition to these cases of influenza, a large number of cases of common catarrh are reported.

As the date of the commencement of the attack of influenza was carefully ascertained and noted down in all the cases which came under my notice, it may be interesting to show the period at which the epidemic attained its greatest intensity. The first case recorded began on the 8th of February, and the last on the 25th of April: the greatest number entered, as beginning on any one day, was on the 12th and 15th of February, on each of which days eleven cases were recorded. The numbers occurring in each week, from February 8th to April 25th, inclusive, are as follows:—

Feb.	8 to	Feb. 14	inclusive	37	cases.
	15	"	21	"	35
	22	"	28	"	33
March	1 to	March 7	"	35	
	8	"	14	"	20
	15	"	21	"	10
	22	"	28	"	7
	29 to	April 4	"	12	
April	5	"	11	"	5
	12	"	18	"	5
	19	"	25	"	8

It appears, then, that the influenza continued without abatement during the three last weeks of February and the first week of March, that it subsided considerably during the following week, and that it progressively declined till the end of April.

The milder cases were treated by Dover's powder, in the dose of ten grains every night, with occasional aperients; the more severe ones by stimulants and narcotics in combination.

Scarlatina.—One case, which occurred in a boy of sixteen, was the mildest which I have yet witnessed. The eruption ap-

peared on one day and disappeared on the next, but without being followed by a single bad symptom. On the day before the eruption, the pulse, in the recumbent posture, was 120; on the day of the eruption, and in the same posture, 116; on the following day 59; and on the two succeeding days 55. It rose to 102 on the seventh day; and in less than a week from that time the boy was admitted into the hospital labouring under anasarca. This low frequency of the pulse is, I believe, an unusual symptom at so early a stage of the disease. The number of the pulse in health, as afterwards ascertained, was about 82.

Struma.—The greater number of cases entered under this head, in this and in the former report, were cases of enlarged cervical glands. Cases of strumous ophthalmia are entered under the head of diseases of the eye; and other scrofulous affections as diseases of the organs implicated.

Podagra.—Some cases, entered under the head of articular rheumatism, belong perhaps more properly to this head.

Ascites.—One case of ascites, occurring in a female, is recorded as having come on immediately after a journey, during which she had to retain her urine rather more than fifteen hours. From that time she made but little water, and began at once to swell. At the time of application there was distinct fluctuation. Her general health was good. The patient was lost sight of.

Pleurodynia.—Many cases of this form of muscular pain, which have presented themselves among the outpatients, were mistaken for pleurisy, and treated by blood-letting. This error has been committed from want of attention, or from ignorance of diagnosis.

The absence of dulness on percussion, the effect of motion and of slight percussion with the points of the fingers in increasing or reproducing the pain, and the absence of all urgent constitutional symptoms, serve to distinguish this comparatively unimportant affection from the severe disease with which it is too often confounded. Under the head of Pleurodynia are included some cases of muscular pain in the abdomen, a form of disease occasionally confounded with peritonitis,

as pleurodynia with pleurisy. The diagnosis, though simple, requires more caution than where the seat of the pain is over some resisting part. Gradual and cautiously increased pressure either relieves, or does not increase, the pain; whilst the slightest percussion with the points of the fingers reproduces the pain, and often occasions the most excruciating agony. The pain is also increased or reproduced by motion. There is one circumstance which is apt to mislead us in applying pressure, and that is, that whilst the hand is still upon the abdomen, some sudden and catching effort of respiration takes place, and, by throwing the muscles into action, produces pain, which an inattentive observer might attribute to the pressure. In applying pressure, therefore, it is necessary to watch the respiratory movements, and to continue the pressure till the respiration becomes perfectly tranquil. Here, as in pleurodynia, the absence of severe constitutional symptoms will materially assist our diagnosis.

The connection of an irritable state of spinal marrow with these muscular pains is very general; and percussion over the spinal processes will generally produce, or increase, the pain in the muscles supplied by nerves from the part which is struck. In some instances, on striking the spinous processes of the several parts of the canal, from above downwards, severe and sudden muscular pains have been produced in the neck, chest, and abdomen, successively. These pains are generally, but not always, confined to one side.

These muscular pains, and the accompanying spinal tenderness, are the last and middle links of a chain of causes and effects, of which the first link is usually found in irritation of the mucous membrane of some of the outlets of the body; as the mucous membrane of the large intestines, of the bladder, or of the vagina. The sequence may be thus stated:—irritation of one of the mucous membranes, spinal irritation, reflected muscular pain. The frequency of this combination should always lead the practitioner to examine the spine when severe muscular pains of the chest or abdomen exist; and, whether spinal irritation be present or not, to inquire minutely into the state of the functions

of the alimentary canal, uterus, and urinary organs. Attention to this class of diseases will amply repay the practitioner.

The treatment must be adapted to the compound nature of the malady. The muscular pain, where it is extensive, may be relieved by opiate fomentations; when confined to a limited spot, by the emplastrum belladonnæ: the spinal tenderness may be subdued by leeches and the tartar-emetic ointment; and the cause of the disease by careful attention to the state of the organ originally affected.

This class of affections is not generally understood, nor is the simple mode of diagnosis here pointed out generally practised. Had it been generally known and used, there is good reason to believe that we should never have had such an unphilosophical term as "false peritonitis" added to our medical nomenclature. I would hazard the opinion that false peritonitis is nothing more or less than severe muscular pain, which is very likely to arise after the violent exertions to which the abdominal muscles are subject during delivery; and the fact that these pains often disappear under the administration of a full dose of opium adds confirmation to this opinion.

Though the diagnosis of muscular pains of the chest and abdomen offers no difficulty provided the examination be made with the ordinary care, and though the treatment is as simple as the diagnosis, it must be borne in mind that severe muscular pains of these parts may be the accompaniments or forerunners of other more serious affections. Muscular pain in the side may be the consequence of violent efforts at coughing, or the forerunner of herpes zoster, as well as an idiopathic affection; or it may precede, or be mixed up with, pleuritis. Pain of the abdominal muscles, again, may arise from violent efforts to vomit, or from extreme distension of any part of the abdominal parietes with flatus, or from repeated efforts to evacuate the bowels, or from similar efforts during parturition.

In all cases, then, it is necessary not merely to ascertain the nature of the pain, but to inquire into its antecedents and accompaniments. The treatment will then present little or no difficulty.

Articular rheumatism.—In the case of a man, aged 40, who had had repeated attacks of the disease, each attack was preceded by a discharge from the urethra resembling that of gonorrhœa. There was no reason to believe that the patient had had repeated attacks of true gonorrhœa.

Chorea.—One case of this disease, occurring among the out-patients, was cured by simple purgatives alone.

Paralysis.—One case of paralysis of the facial nerve of the left side, occurring in a male, aged 25, first seen November 16, was discharged, cured, December 2, after abstraction of blood by cupping to the back of the neck to the extent of $\text{ʒ} \text{iv}$., followed by bleeding from the arm to the same amount, and a blister behind the ear. The only medicines given were simple aperients. The paralysis was succeeded by an herpetic eruption over the entire surface.

Melancholia.—One case of melancholia presented a character which is not uncommon, and which, when heightened and confirmed, constitutes a form of moral mania. The patient, a married woman, $\text{æ}t.$ 45, in consequence of anxiety of mind, had fallen into a state of extreme depression of spirits, accompanied by constant apprehension. She stated that whatever crime she heard of, or read of, she felt a strong temptation to commit, accompanied by an equally strong fear of committing it; and that it was impossible to state the dreadful things that entered into her mind. She added, that any violence, of tongue or hand, to her children, or any one about her, would be a great relief to her, and that she had the greatest difficulty in restraining herself. The patient gradually recovered by taking a combination of dilute sulphuric acid, tincture of opium, and digitalis, with infusion of quassia; the bowels being kept open by gentle aperients.

Cynanche tonsillaris.—This disease in its early stage is accompanied by a frequency of pulse greatly disproportioned to its severity. Thus in a man, aged 25, about thirty hours after severe shiverings and pains in the back and limbs, the pulse was, standing 148, sitting 140, and lying 132. Respirations, in the recumbent posture, 28. The pulse, in this disease, as at the outset of all marked febrile affections, is full, soft, and quick.

Tonsillitis.—Cynanche tonsillaris and tonsillitis are here distinguished. Cynanche tonsillaris is a severe febrile affection with a local inflammation; whereas common inflammation has nothing of a febrile character, but is a simple local complaint. Under this term the relaxed sore-throat is included, as also those cases which cannot be distinctly traced to a syphilitic source.

Bronchitis.—Two cases of bronchitis senilis occurred in men who had passed their ninetieth year. One of the two stated that for the last seventy years he had taken neither beer nor spirits, and had lived constantly in London without a single interruption of his health. His employment was that of an heraldic draughtsman and engraver: he had had two wives, and twenty-two children.

Phthisis.—The report confirms the statement of last year as to the excess of males afflicted by this disease. One case illustrates the necessity of not trusting to the senses where an accurate measurement can be made. A lad, $\text{æ}t.$ 20, received a stab on the right side of the chest, followed by consolidation of the lung of that side. The appearance of the chest was remarkably deceptive: the right side appearing the larger, but being in reality the smaller by half an inch.

Asthma.—In one case of spasmodic asthma there was considerable tenderness in the upper part of the dorsal vertebræ, and the fits were preceded by a degree of flatulence unusual even in this disease.

Palpitation.—In one case the palpitation followed an attack of gout: there was no bruit. The pulse in the erect position was 150, sitting 146, and lying 140: respirations lying, 29. In another case the pulse was 166, sitting. The slight effect of change of posture, which I have already pointed out as occurring in phthisis pulmonalis, is probably present in all cases of increased frequency due to an irritable state of the muscular structure of the heart itself. I have reason to believe that the frequent pulse of consumption is due to this cause, and not to the existing febrile state of the system. It will be seen that in the case of cynanche tonsillaris already alluded to, the effect of change of posture on nearly the same frequency of pulse was double that occurring in the case of palpitation.

Gastro-enteritis mucosa, the so-called

English cholera.—One of the most severe cases which I have witnessed occurred in a man æt. 40. When he first presented himself he vomited and purged every three or four minutes; had violent cramps of both extremities, with the most acute pains, especially in the calves of the legs; and the hands were violently contracted, the fingers being forcibly bent upon the palm. He had been ill for fourteen days, but his symptoms had reached their acmé two days prior to his application at the hospital. He was ordered to take nothing but milk gruel for one or two days, and a draught consisting of mucilaginous mixture, with twenty drops of tincture of hyoseyamus, three times a day. On the second day he was much better; and from that time rapidly recovered. The majority of cases of this disease require nothing more than a strict farinaceous diet, with stimulants and narcotics, if great debility is present.

Constipatio.—In one case (that of a female aged 40), as many as sixteen days were passed without relief, and on many previous occasions a week or ten days; but, nevertheless, the tongue was but slightly furred, and the chief complaint was debility.

Colica pictorum.—This disease occurred in one instance in the person of a fishmonger, whose hands were constantly moistened with the brine in contact with the lead-covered counter. The blue line was distinctly marked on the gums.

Tabes mesenterica.—The small number of cases of this disease which have been entered on our books is a subject of great congratulation. If my recollection of the diseases occurring amongst patients of the same rank of life twelve or thirteen years since may be depended on, I have reason to believe that this formidable disease is becoming more and more rare: at any rate, the present uncommon occurrence of this disease, and of other severe diseases of infancy, contrast strongly with Fordyce's vivid description of the 30,000 children in London and Westminster labouring under hectic fever in its worst form, with emaciated bodies, tun-bellies, swollen hands and feet, and distorted limbs. Seven cases of hydrocephalus, two of tabes mesenterica, and eleven of mollities ossium, in upwards of 8000

patients, is a very favourable catalogue of the severe diseases of infancy.

Icterus.—Among these nine cases there was one well-marked case of icterus infantum. The child was born on Thursday night, at ten o'clock, and the disease made its appearance on Saturday at noon. The skin was universally of a deep-saffron hue, the conjunctiva slightly discoloured, and the face deeply tinged with bile; the urine of a natural colour. The mother was free from the disease. The complaint disappeared in four days under the use of minute doses of hyd. c. cretâ, and castor oil.

Incontinence of urine.—Three cases of this disease occurring in young persons have fallen under my notice during the last year, and one during the present, all of which have been promptly relieved, and ultimately cured, by tincture of cantharides in combination with tincture of opium or hyoseyamus. The only case reported as occurring in the female happened in a girl, aged thirteen, who applied for advice April 1st. She stated that she retained her urine well in the recumbent posture, and at night, but had no power over the sphincter in the erect and sitting postures. She was ordered—

Tinct. Cantharidis, ℥ij.; Tinct. Opii, ℥v. quater quotidie; Pil. Rhei c. gr. v. o. n.

15th.—Has improved regularly and rapidly, and during the last three days has been free from the complaint. She was ordered to continue the medicines to prevent a relapse, and on the 4th of May was discharged cured.

Another case occurred in a boy, æt. 15, who applied Nov. 23, 1841. He stated that he could not retain his urine longer than an hour at a time, and that he was obliged to rise three or four times in the night to void his urine, and that he frequently passed it in bed unconsciously. Ordered—

Tinct. Cantharidis, ℥ij.; Tr. Hyoseyami, ℥x. quater quotidie.

27th.—States that about five minutes after taking each dose of the medicine, he feels a cutting pain in the bladder, which lasts about five minutes. He holds his water three hours instead of one, and gets out of bed once instead of three or four times. He has ceased to pass his urine unconsciously.

RESEARCHES ON THE DISEASES OF THE HEART AND ARTERIES

Dec. 2d.—Still continues to retain his water better by day, but is again disturbed more than once during the night. Ordered

To take three drops of the Tincture of Cantharidis, and fifteen drops of the Tincture of Hyoscyamus, every night, and to continue the former dose throughout the day.

7th.—Continues better in the day; but in the same state at night.

13th.—He is now obliged to get out only once during the night. He was ordered to continue the medicine, and before the end of the month was discharged quite cured.

The same result has followed the use of the same remedies in the third case of last year, and in the one treated during the present year.

Eczema rubrum.—One case, occurring in a shoemaker, aged 51, was treated by antimonio potassio-tartras in the dose of an eighth of a grain in combination with one grain of the hyd. c. cretâ four times a day.

The case was one of great severity, and the patient had, on many previous occasions, suffered very severely. The patient first applied on Aug. 6th, and on the 26th of the same month was nearly well, having, according to his own statement, never derived so much benefit from any other medicine.

Sept. 3d.—Cured.

Herpes.—The most severe and extensive form of this disease which I have witnessed occurred in a stonemason, aged 27. The eruption existed on the lips, nose, cheeks, forehead, penis, and buttocks. It appeared during the night, and was accompanied by a white tenacious secretion on the tongue. The disease always comes on after drinking freely of beer, or taking as little as two glasses of gin.

Amenorrhœa.—A patient, æt. 32, in whom the menstrual discharge was nearly suppressed, stated that she had violent sneezing and running at the nose at each menstrual period.

The foregoing observations are either extracted from the column of remarks appended to the register of my own out-patients, or they are more general results of experience founded upon the large number of patients constantly applying for advice—a number continually increasing, and affording a

very wide, though, in some respects, an imperfect, field of experience. The annual report promises to increase in completeness, and, consequently, in interest, with the improved registration of the in-patients now adopted. Imperfect as the present report is, I have thought it better to publish it than to allow the habit of collecting facts on the large scale to fall into disuse.

RESEARCHES

ON THE

PATHOLOGY, PHYSICAL SIGNS,
AND DIAGNOSIS,

OF

DISEASES OF THE HEART AND
ARTERIES,

IN CONNECTION WITH

THE SOUNDS OF THIS ORGAN.

By T. H. MOORE, A.B. M.B. T.C.D. &c.

(For the Medical Gazette.)

THE obscurities which at present pervade the subject of aneurism in its incipient stage, induce me to publish the following cases and observations, in the hope that some advantage may result therefrom to the profession in general.

CASE.—Permanent patency of the aortic aperture from dilatation of the aorta, and slight thickening, with induration, of the valves; incipient aneurism formed in the muscular parietes of the left ventricle; three varieties of aneurism exhibited in the course of the aorta—the true species, from its origin to that of the arteria innominata, the calibre of the artery being dilated, without any breach of surface, but with fibro-cartilaginous deposits in its coats. Secondly, fusiform dilatation at the origin of the arteria innominata, with a small pouch from thinning of the coats of the vessel; a circumscribed false aneurism, formed at the posterior part of the arch, producing, by its pressure, absorption of the vertebræ. Heart's action accompanied by a loud "buzzing," sometimes "creaking, or rasping murmur;" ascites, anasarca, disease of the liver with an emphysematous condition of the stomach, &c.

A private (David Kenny) in the 47th regiment, 35 years of age, was sent to Dublin, from the General Hospital,

Cork, to be brought before the Kilmainham Board, and discharged the service.

When admitted into the General Military Hospital, Phoenix Park (August 25th, 1841), he was suffering so severely from dyspnoea and orthopnoea, that he could not remain at rest in the recumbent posture, but was forced to sit, propped up in bed, to alleviate, in some degree, the sense of suffocation, which was extremely oppressive. His face was puffed up, œdematous, and congested; conjunctiva vascular, and tinged with bile; neck short and swollen, with turgescence of the veins; cellular tissue of the hands, arms, and lower extremities, infiltrated with serum, so that deep pittings in the integuments were produced by pressure. He complained chiefly of shortness of breathing, harassing cough, with ropy phlegm; a "dragging weight" about his heart and chest; sleepless nights, from startings and unpleasant dreams; loss of appetite; some thirst.

Physical signs of the chest, heart, and arterial system.—The chest, of capacious size, was heaved forcibly during respiration, but not equally dilated during the motions of each side; the superior part of the right being more energetic in its action, whilst inferiorly there was more fixedness of the intercostal muscles and ribs than was observed on the left side: from the antero-superior part of the right side, percussion elicits a clearer sound than from the left, which is not only comparatively, but absolutely, dull from the second intercostal space downwards: the respiratory murmur is supplementary in the right lung, over the extent of surface, from which a clear sound is obtained; about an inch below the inferior margin of great pectoral muscle, the supplementary character of the vesicular murmur ceases, its intensity abruptly terminates, and is replaced by the non-terminal respiration, the inspired air not penetrating into the vesicular tissue, nor minute bronchial tubes, but arrested in those tubes from which the terminating branches derive their origin. This description of respiration merges into that of a more defined bronchial character, assuming an increased degree of intensity as we approach the lateral and posterior portions of the side, where the degree of dulness on percussion is absolute, com-

mencing at the scapular spine, and extending to the lowest part of the side; the suppression of the vesicular murmur, and its replacement by semi-bronchial and bronchial respiration, accurately coincide with the loss of sonoreity on percussion. The tubular or bronchial respiration appears to have attained its maximum of intensity at a short distance from the inferior angle of the scapula, the escape of air during expiration being more marked, and attended with more resonance, than its entrance into the tubes during inspiration; below this its distinctness decreases, its intensity fades away, and at the most depending parts it is almost extinct. The resonance of the voice, superiorly, communicated to the hand, is perceptible, but not strong; upon the ear it strikes with force, and is bronchophonic; below the scapular spine the voice is broncho-ægophonic, being accompanied by slight tremulous undulations in its passage through the stethoscope; whilst over the inferior and lateral parts it becomes distinctly ægophonic, so that the successive bleedings of the voice, in their transit, resemble very much the squeaking of a punchinello. In the lowermost portion of the side this physical sign becomes less distinct, and, like the bronchial respiration, extinct. The presence of crepitation could not be satisfactorily ascertained, except during a paroxysm of coughing. In the supero-anterior division of the left side the respiratory murmur is clear, and of normal strength, though not so loud as in the opposite lung, being audible for three or four inches below the subclavicular region: it ceases to be heard in the cardiac region, and cannot be detected until we arrive at the posterior aspect of the chest; here, as well as on the right side, there are evidences of an effusion into the pleural cavity, not extending higher than the inferior angle of the scapula, and, consequently, not so considerable in quantity.

An exceedingly dull sound is elicited by percussion over the cardiac region, extending far beyond its limits; so that the inferior and middle divisions of the sternum have lost their sonoreity. This extent of dulness cannot be attributed altogether to displacement of the mediastinum by the effusion into the right pleural cavity, as the heart's impulses are diffused and felt over double the

extent of surface that is usual—not violent nor strong, but dull and laboured; so that, at each stroke, the chest is heaved, the sternum is shaken, and the epigastrium quivers. These heaving motions of the chest appear to the eye, viewing them in a horizontal direction, to originate in the action of an entire organ; not of a particular part. A slight thrilling sensation is experienced by the hand applied beneath the mamma; but over the sternum the vibratory, purring thrill, or twanging sensation, is much stronger and more evident. The action of this organ is laboured; sometimes it seems as if it were convulsed, or on the point of being totally arrested. The several parts composing the heart's rhythm are so completely obscured by a loud "beetle-buzz" murmur, that it is impossible to distinguish them individually, or recognize them collectively; to pronounce when the first sound begins, or the second ends; when the ventricular contraction has commenced, or the diastole has terminated: all—first and second sounds, systole, diastole, and interval—seem involved in, and replaced by, this abnormal "beetle-buzz murmur." Below the nipple this sound is rather indistinct, not exceeding a bellows-murmur, which creates in the mind the idea of its being deep-seated, or situated at a distance from the thoracic parietes. Approaching the sternum, this bellows-murmur seems to be more superficial, somewhat roughened or rasping in its character, but not having attained its maximum of intensity until examined midway between the fourchette of the sternum and the xiphoid cartilage, where an unceasing train of these abnormal murmurs, varying in degrees of intensity, follows in regular succession. They were reported to commence with a loud rushing, deep-cooing, and filing sound, assuming, towards their termination, a more roughened, rasping, and rather creaking character; resembling, but not amounting in roughness to, a pericarditic friction sound. The deep-seated and superficial arteries of the neck and upper extremities may be seen bounding in their places. This violent throbbing, or jerking pulsation, of the arterial system is visible at some distance from the bed; so that, when the arms are extended, the brachial and radial arteries are observed to

vibrate with energy, and elevate the integuments, although partial œdema of the hand and wrist exists. After the column of blood has been propelled into the arterial trunks, the vessels have been observed to dilate with force, and again collapse; but in the intermediate stage, between the complete dilatation and total collapse, a slight contractile or vermicular motion takes place, commencing in the smaller, and extending along the larger arterial trunks: during this action a reflex current of blood can be distinctly traced with the eye, traversing these vessels from the distal towards their cardiac extremity. In the course of the aorta, subclavian and carotid arteries, also along the spine posteriorly, an intense forward whizzing murmur is communicated to the ear, comparatively prolonged in its duration and uninterrupted in its succession, followed by a backward, regurgitating bellows-murmur. From the alternations in character which these abnormal murmurs are occasionally observed to undergo, it was conjectured that the advancing column and retrograde current of blood meeting, coalesced, and gave origin to the increased loudness and roughness in the stethoscopic phenomena. Pulse 108 per minute; respirations 44. The abdomen is distended, in consequence of the stomach and intestines containing flatus; the presence of fluid, also, was ascertained by percussing the abdominal parietes. The hepatic dullness on percussion extended beyond its normal limits; the surface of the liver is indurated, and its edges rounded. The scrotum is enormously swollen, the infiltration of serum into the cellular tissue of penis and scrotum being immense; the integuments are tense, glossy, semi-transparent; the weight of the genital organs increased; the passage of urine is not obstructed by the distorted, corkscrew shape of the penis; its secretion is scanty, high-coloured, but free from albumen.

History.—Seven months from the period at which this report was taken, he was performing his duty as an efficient soldier; the disease under which he labours being ushered in, after cold, or exposure to the night air, by violent palpitations, shortness and difficulty of breathing, pains in the chest; so that it is probable acute inflammation of the heart, its internal or external lining

membrane, existed. Subsequently the feet swelled; the œdema spread upwards to the legs, thighs, and abdomen. Coincident with the increase of the ascites and anasarca, he noticed a corresponding diminution in the secretion of the urine; its quantity varied at different times. His complaints have become aggravated since he left Cork, the cough being more harassing; expectoration glutinous, tenacious, streaked with blood; and the anasarcaous swellings more generally diffused.

V. S. ad 3xii. Cupping to the right side.

R. Digitalis in powder, gr. j.; Squill in powder, gr. j.; Calomel, gr. ij. Mix. To be taken three times a day in the form of a pill.

27th.—Has experienced much relief from the venesection and cupping, so that he can breathe with greater freedom, and is not oppressed by the constriction of the chest and the heavy dragging sensation hitherto felt about the cardiac region; the swellings are diminished; the cough not so distressing; the expectoration still viscid, and tinged with blood; respirations 32, not so laboured, the chest expanding with more ease. With the exception of the dulness on percussion being partially removed in the superior parts of the right side, but little alteration can be said to have taken place in the physical signs. Since the abstraction of blood, the bellows-murmur, which was indistinct, and deep-seated at the left side of the heart, seems to be more superficial, and increased in loudness. Pulse 104, unaltered in character.

Continue pills. To have a quart of Cream of Tartar drink in the day. Scrotum to be punctured with a fine needle.

29th.—The quantity of serum discharged from the scrotum has been considerable; although the dribbling has been constant, yet the distended state of the integuments remains, forming between the thighs a large tumor, with slight patches of inflammatory redness and excoriation, the result of irritation, caused by the continual contact of the moist scrotum with the skin of the thighs. No displacement of the raphe has taken place from the infiltration of the cellular tissue being universal. The superior parts of the lungs are more permeable to air; crepitation is more distinct; bronchial res-

piration not so well marked; the inspiratory and expiratory motions of the lung are attended with the friction sounds, which are partially confused with the crepitus; the hepatic enlargement can be detected by a gentle, but quick, tapping over the liver with one or two fingers, which, by displacing the fluid, arrive at the solid indurated viscus. By carrying the fingers to the right and left from this point, its outlines can, with some degree of accuracy, be traced; as well as by the extent of dulness on percussion.

Repeat pills, &c.

Sept. 1st.—In addition to the physical signs reported, an extensive and well-marked friction-sound is audible in the cardiac region, in part connected with the respiration, in part with the heart's action; much coarser between the nipple and sternum than elsewhere.

Let a blister be applied to the left side.

Medicines to be repeated.

11th.—This morning he suffers dreadfully from a sense of suffocation, oppression, and weight about the chest; his pulse continues quick, full, and throbbing; breathing laboured, hurried, heaving; countenance bloated, congested, and expressive of great anxiety. The results of auscultation vary in a slight degree from those hitherto recorded: the accumulation of fluid in the abdomen has increased, this cavity being full and distended to a painful degree, fluctuation being evident on percussing its parietes. It was now decided upon, in consultation, that the urgent request of the patient should be acceded to, in performing the operation of paracentesis. From two to three quarts of limpid fluid were withdrawn, the removal of a greater quantity not being deemed advisable: some hæmorrhage ensued after the operation, but was checked by compresses: his strength was supported by nutritious diet, and the following medicine ordered—

Camphor Mixture, ʒvi; Elaterium, gr. i.;

Spirit of Nitrous Ether, ʒii.; Mix.

An ounce to be taken every fourth hour.

Electuary of Cream of Tartar.

15th.—Some temporary relief has been afforded by the operation; there has been a constant dribbling or oozing from the puncture, so that the quantity of fluid thus discharged has probably

exceeded that originally withdrawn ; the gums and breath betray evidences of mercurialization ; secretion of urine more copious ; anasarcons condition of the scrotum and penis diminished ; the integuments are loose, thickened, and have a welted appearance ; the dyspnœa and orthopnœa continue urgent ; cough frequent ; expectoration copious, and viscid ; the loss of sonoreity on percussion is as obvious as when admitted ; the heart's action tumultuous ; bellows-murmur loud, and extensively heard ; along the sternum the character of the double-dash, regurgitating, whizzing murmur, imparts to the mind the idea of the advanced and advancing column of blood, propelled with enormous force, being arrested, retroceding, and coalescing with the progressing column of blood. From the confluence and subsequent commingling of these sanguineous streams, a sudden splash, or double-dash, ensues ; an instantaneous convulsive action of the entire organ succeeds : a series of ineffectual attempts is made to surmount this disturbance, which appears to be overcome alone by the laboured action and energetic force, propelling forwards the contents of its cavity with a deep cooing, whizzing, and beetle-buzz murmur : pulse 104 : the physical signs, produced by considerable liquid effusion, remain as noted on admission.

18th.—Is evidently yielding to the disease ; face more swollen, of a bluish leaden colour, with a tinge of yellow ; the conjunctiva and skin present a subjaundiced hue ; he lies on the right side, with the arms extended ; ears and lips of a livid colour, purplish patches diffused over different parts of the body ; neck tumid ; veins turgid. Since last report he has been dull and stupid, but retains his mental faculties, complaining of his being racked to pieces by the cough-palpitations ; his appetite has failed ; thirst increased ; he seems to be aware of his approaching end.

23th.—Died yesterday at 3 A.M.

*Autopsy 24 hours after death :—*The external appearance of the corpse is such as I have seldom witnessed, and almost baffles description : the face immensely swollen ; features distorted : from their congested appearance, also from the lividity of the ears, lips, and nose, as well as from the engorged

state of the venous trunks, it was conjectured that he had suffered extreme agony in the last moments of life : the ramifications of the abdominal and thoracic veins being so prominent that they can be distinctly traced, cause the surface to present a marbled aspect : the sides of the abdomen exhibit different shades of red, in some parts bright scarlet, which, deepening in colour, assumes a purplish tinge : scattered here and there indiscriminately over the chest and abdomen, the latter in particular, are variously-sized circumscribed spots, some of deeper, others of lighter red, clustered together in greatest numbers above the pubes and in the groins, which do not disappear on pressure ; some excoriation of the scrotum and the inside of the thighs, with a few semi-gangrenous spots on the former, and a swollen, red, and twisted shape of the penis, near the corona glandis ; the lower extremities are comparatively free from œdema ; a few vesications have formed on the posterior parts.

The increase of size in the dimensions of the thorax was mainly attributable to an enlargement of the right side. As soon as a puncture was made into the pleural cavity, straw-coloured fluid instantly rushed out ; the quantity which thus escaped being considerable.

On raising the sternum, the pleural cavity of each side appears shortened in its vertical measurement, by the encroachment of the liver on the right side, and the distension of the stomach in the centre, and on the left ; the convexity of the stomach being unusually high in the present instance : the inferior and posterior part of the right pleural cavity is occupied by a brownish-coloured fluid, which fills up the intermediate space of two inches, between the lung and the diaphragm. The middle lobe, widely separated from the inferior, which lies compressed at the posterior and lateral portion of the side, is coiled upon itself, and overlaps the lower part of the superior lobe ; these divisions of the lung being pushed upwards and forwards by the fluid accumulated behind, so that the surface naturally in contact with the inferior lobe is anteverted, its aspect looking forwards, and in contact with the intercostal pleura, whilst the anterior surface is retroverted, and directed posteriorly, being in contact with, and

slightly agglutinated to, the surface of the middle and superior lobes. By separating these adhesions, the surfaces which had been approximated exhibit a reddish colour from the vascular network: discolouration of the pleura, and slight exudation of plastic lymph, which exists in greater quantity at the edges than at the centre, and is more advanced in organization, although of recent formation; the intercostal and diaphragmatic pleuræ, also, are roughened by the exudation of lymph, flakes of which float about in the fluid, and are collected into masses at the most depending part of the cavity: in the left pleural cavity, some straw-coloured serous fluid has gravitated to the posterior part; from two to three quarts were contained in the right, scarcely a pint in the left, pleura.

The mucous membrane of the larynx and trachea is congested; about the root of the tongue and the epiglottis it is tumid, partial infiltration of serum into the cellular membrane having taken place; the rima glottidis remains unaltered in shape; the subdivisions of the bronchial tubes are affected with different degrees of inflammation; the right lung retains, in its superior lobe, its crepitating character, and normal degree of elasticity, but of these there is a great deficiency in the middle, and an almost total absence in the inferior lobe, in consequence of the atonic state of the pulmonary structures, and compression exercised on the vesicular tissue by the accumulated fluid: the pulmonary tissue was not much engorged with blood, nor with serum, but compressed and condensed, so that the lung, although diminished in volume, did not resemble in its solidity a pneumonic or hepatized lung; when incised it presented a dark livid colour, not unlike the transverse section of a placenta: the interior of the veins and arteries was deeply tinged with blood; the left lung, partially affected in the lower lobe, has evidently been the chief organ in carrying on the functions of respiration.

A notable alteration in the position of the heart has been produced by its enormously enlarged condition, and an effusion into the pericardium, rendering tense this envelope, and stretching it across the diaphragm, so that the body of this organ occupies the inferior and

middle parts of the mediastinum: its apex and base, instead of being situated obliquely with regard to each other, are directly opposed, the former occupying the left pleural cavity, the latter situated in the right, and in contact with the coiled portion of the middle lobe: the external surface of the pericardium possesses in some places a crimson colour; minute vessels are seen to branch off in different directions: when laid open, a tea-cupful of serous fluid was removed, which, with opacities and slight roughness of the membrane, were sufficient evidences of a subacute inflammation of the pericardium. The auricular and ventricular cavities appeared to be enormously distended with coagulated blood, so that in weight and size it nearly equalled an ox's heart: the veins on the anterior and posterior aspects of this organ were gorged with fluid blood; its weight, when partially freed from the coagula, exceeded $2\frac{1}{2}$ lbs. avoirdupois. The augmented volume of the heart is manifestly attributable to an unusual degree of hypertrophy of the parietes of the left ventricle, with dilatation of the cavity in its vertical and transverse measurement. The apex, usually well defined in the normal condition, presents a rounded, obtuse shape, which is dependent upon the abnormal enlargement of the ventricle; on the anterior aspect, situated about the centre, and apparently in the substance of the septum, is a projecting conical tumor, firm to the touch, slightly moveable, seemingly the result of a collection of fibrine, but produced by the bulging of a hypertrophied carnea columna. In completing the transverse section of the heart, about two inches from the apex, and slitting up the ventricles, it was found that the hypertrophied muscular substance of the left measured from eight to ten lines, which degree of thickness was considered to be uniformly retained, except near the apex, at the posterior aspect of the ventricle, where the muscular substance was evidently more flabby, much thinner, and differing in colour from the surrounding parts; circular in form, circumscribed in extent, and corresponding in its diameter to that of a sixpence: when pressed on from the exterior, no resistance is offered, the attenuated muscular fibres yield with the greatest facility, so that

the finger protrudes into the interior of the ventricle, through a species of cul-de-sac encircled by the surrounding hypertrophied muscular fibres. In examining and pressing from the interior of the ventricle, an evident bulging, or conical projection, is formed externally, which cannot be produced in any other portion of the ventricle; from which alterations in the appearance and density of the muscular structure it was inferred that an incipient aneurism of the ventricular parietes must have originated in, and coexisted during the patient's lifetime, with the morbid changes progressing in the heart; the endocardium of the aneurism being continuous with that of the dilated ventricle. This aneurism, towards the termination of the case, may have formed a projecting tumor during the systole and diastole of the ventricle. The cavity of the ventricle is capable of containing a moderately-sized healthy heart, or large-sized orange; its interior presents an intricate interlacement of the muscular fibres, the fleshy columns having apparently multiplied in number; those, at least, which are passed unnoticed in other hearts, have become so much developed as to attract particular attention; the fleshy columns to which the tendinous cords are attached are increased in thickness, as are also the latter; the mitral valves retain their transparency and healthy aspect; their size is nearly proportionate to the diameter of the auriculo-ventricular aperture, but from the width of this aperture viewed through the auricle, from its measuring three inches, and admitting the four fingers held transversely, also from the facility with which fluids pass through this opening into the auricle, it was conjectured that passive dilatation of the orifice, with insufficiency of the valves to effect its perfect closure, must have existed. The cavity of the auricle is dilated, the parietes somewhat more dense than usual; but no traces of chronic inflammation can be detected in the interior; the endocardium is deeply tinged with red, perhaps from imbibition the appendix dilated, and its muscoli pectinati well developed. The remarks made with regard to this auricle and valves apply equally to the right. The cavity of the right ventricle is encroached upon, and diminished, by the bulging of a

hypertrophied septum, which, being arched, is convex towards the right, and concave towards the left ventricle.

The aorta, in the ascending, middle, and descending divisions of its arch, was dilated to double or treble its normal calibre, so that it formed an unusual bulging in front of the trachea, and compressed several of the large and small intra-thoracic veins, the coats of which were increased in density, and the free circulation of the blood obstructed. From its origin, to three inches below the termination of its arch, the coats of the vessel are thickened; the internal lining membrane is discoloured, presenting in several places patches of vascularity, and yellowish-white specks. It possessed none of the smooth glistening polished surface so striking in the healthy artery; but was thickened, uneven, corrugated, and elevated, in some parts, into circular projections. Corresponding to these yellowish discolourations, the lining membrane can be detached with the greatest facility by passing the edge of the scalpel, or touching the part with the point of the nail. There seems not to be the least attachment between it and the coat underneath. Beyond its limits, the adhesion between the internal and middle coats is so firm, that it requires some force to separate them; the surface of the middle coat, viewed through a microscope, exhibits a yellowish colour, granular appearance, with depressions and elevations. A few ossific deposits were situated in the middle coat, without having produced a rent in the lining membrane. The increased thickness of the coats of the artery is attributable to a hypertrophied condition of the middle tunic, which, when exposed by removing the lining membrane, possesses the characters and appearance of being formed by distinct and well-developed muscular fibres, apparent without the aid of a microscope; but when viewed in their magnified state, their existence is rendered indisputable. With some degree of caution, and slight forcible traction, these muscular fibres were divisible into three separate layers; the two first of which, consisting of the internal and middle layers, had a quantity of fine condensed cellular membrane interposed: the distinction between the second and third layers was not so

attainable, as much difficulty was experienced in effecting their separation. The direction which the hypertrophied fibres assumed was pronounced to be threefold—longitudinal, circular, and oblique; the interlacings of the latter produced, in many places, an obscurity in the arrangement of the former. In those parts corresponding to the yellowish discolourations, the continuity of the fibres was interrupted, and not unfrequently destroyed, the external tunic being visible underneath. The *arteria innominata* was dilated in its calibre as far as its bifurcation into the carotid and subclavian; its coats thickened, except at its origin, where, from the attenuation or atrophy of the structures of the vessel, they were perfectly diaphanous, in an extent of surface equalling the circumference of a sixpence. Complete absorption of the fibres of the middle coat, so well developed in every other portion of the arch, was considered to be the cause of the diaphanous state of the *arteria innominata* at its origin. The internal and external coats were perfect. At the posterior part of the arch, immediately behind, and at a short distance from the left subclavian artery, is a well-defined aneurismal pouch, capable of containing a small-sized walnut, with a capacious circular aperture, smooth and glistening; the lining membrane of the artery and aneurismal pouch being continuous.

The apex of this globular sac was much thinner than at the origin of the sac. Externally, it was adherent to the sides of the bodies of the third and fourth dorsal vertebræ, which presented deep indentations—the consequence of absorption produced by the pressure of the aneurismal pouch.

In the abdomen some fluid was contained, scarcely amounting to a quart. No traces of peritoneal inflammation could be detected. The stomach, which was distended to a great degree, did not collapse, as in ordinary cases, when the œsophagus was cut across two or three inches above the cardiac orifice. By its distension, the diaphragm was pushed upwards, and the left pleural cavity encroached upon. The tense state of the muscular fibres of the diaphragm was rendered more remarkable, as the reverse might have been expected from the effusion into the pleural cavities, and the hypertro-

phied condition of the heart. The other intestines were slightly, but not proportionably, distended with flatus; the transverse colon being more free than usual. The stomach, when laid open, contained a quantity of thick pulpy greenish-coloured substance, which was collected into a mass at its left extremity. The interior of the stomach exhibited a very remarkable and beautiful pathological specimen of extensive submucous cellular emphysema, occupying the anterior and posterior surfaces, great and small curvatures of this viscus.

The air, which was infiltrated through the submucous cellular tissue, caused the mucous membrane to be elevated into large vesicles, several of which were grouped together in the form of clusters, of a greenish-white colour, downy feel, and frothy appearance, like a number of soap-bubbles floating on the surface of water. The mucous membrane thus separated from the muscular coat formed, in several places, a prominent surface, elevated above that in its vicinity from a more extensive infiltration of air into the cellular tissue; also from rupture of the cells, and consequent coalescence with each other. The interior of the organ thus affected had lost completely its normal characters; the rugæ, mucous follicles, and gastric glands, being thus rendered indistinct and obliterated by this gaseous exudation or secretion into the cellular membrane. Towards the pylorus, the air-vesicles were less numerous, discrete, and slightly elevated, in consequence of the integrity of the cells, and their non-communication with each other. The mucous membrane here retained its pale colour, and smooth soft villous surface. By pressing the coats of the stomach between the fingers, the crepitation of air was rendered obvious, not only to the sense of touch, but also to that of hearing; so that, by subjecting the larger lobules and clusters to an ordinary degree of pressure, and by passing the scalpel lightly over their surface, the crepitation thus occasioned resembled the crackling so perceptible in the cellular tissue of the neck and thorax after fracture of the ribs, with injury of the lung. Externally, the bulging of the left or emphysematous extremity of the stomach was pronounced to be much greater

than natural. When thrown into water, the entire organ floated buoyant on the surface, whilst other portions of the intestinal canal sank.

This disease was limited in its extent, as no trace of it could be discovered in any other part of the intestinal canal. The duodenum, the cæcum, and its valves, were healthy; the liver was weighty, enlarged, indurated; its mottled incised surface, of brown and white, corresponded, with tolerable accuracy, to the colour of a grated nutmeg.

[To be continued.]

CASE OF
BLUE DISEASE, FROM A RARE
MALFORMATION OF HEART.

By JAMES DOUGLAS, Esq.

Member of the Faculty of Physicians and Surgeons of Glasgow, Lecturer on Anatomy, &c.

(For the Medical Gazette.)

—
ANY malformation of the heart, permitting the venous blood to mingle with the arterial, before the distribution of the latter to the system, will produce the "blue disease," and we find that the most frequent cause of this commixture is the patency of the *foramen ovale*. In the following case the anatomical cause of the disease was very different from what we usually see; indeed, I cannot find an instance precisely similar on record. Besides, as the case occurred in my own family, and was watched with the most painful interest, the account which I can give of it should be more than usually full and correct.

My little son, Thomas Douglas, was as plump and firm as other children at birth (Sept. 4, 1840), only so dark coloured that the nurse thought he had been half strangled by the cord, which was twice round his neck. When about four months old, his mother wondered that his skin had not cleared, and began to think that he was peculiarly blue in his colour at times. It is truly said that mothers have keener eyes than any one else, with regard to their offspring, for I could not, or would not, see any thing uncommon about him for a long while after this. He throve well, and was good-tempered, and smiled, but he never laughed loud, nor exhibited any glee, like most in-

fants. It was when seven or eight months old, that I first was persuaded of the general dulness of his skin, and the purple hue of his lips and nails, and that I remarked the occasional aggravation of this when crying, and on certain days, even without such exertion, into positive lividity. More recently, at such times, dark blue veins might be seen in his fingers and toes, and even in his lips and nose, perfectly distinct, while the capillary vessels, being equally dark, gave the whole a deeply livid tint. His pulse and respiration were very variable, sometimes very slow, and sometimes very frequent. When oppressed, the respirations were 48 in the minute, and were drawn quickly to the full, were retained full for an instant, and then expiration took place more gradually. Nothing abnormal is detected by listening to his chest, the sounds of the heart being quite natural and regular.

Teething commenced in June. The two central incisors of the upper jaw first appeared, then the two central below, then the two lateral above, then the first molar above, then the first molar below, while the lower lateral incisors had not come through up to the period of his death. This irregularity, being attended as usual with considerable constitutional disturbance, of course aggravated the symptoms arising from the state of his circulation.

In July he had a bad fit, of a convulsive nature, which lasted for nearly two hours: he was in the country, and by the time I arrived he had fallen into a quiet sleep. It left no bad effects behind. About a week after, he had another, but slighter, and three weeks after this a third. The warm bath was used while he was in each, and a clyster administered. About the beginning of November, just after returning to town, he had one, about 2 p.m. I happened to come in just as he took it, and it was the first that I had seen him in. He was quite insensible, with a good deal of convulsive action of limbs, some foaming at the mouth, no distortion of face, but the pupils turned upward, quite out of sight. On the convulsions ceasing, in about a quarter of an hour, he remained insensible, but calm, the pupils still turned up, the face pale, the breathing slower than usual, the skin cold and perspiring profusely, the pulse not to be felt at the

wrist. He was put into a hot bath for five minutes, and had six or seven ounces of warm soapy water with two tea-spoonfuls of turpentine injected, which brought away a deal of wind, and but little feculent matter. In two hours he opened his eyes, and became sensible, appeared very thirsty, took some drink, and seemed much exhausted, but did not sleep till seven in the evening. Five days after this, about 9 p.m., he had a fit, but without convulsions, and remained insensible for two hours and a half. Towards the end of that time, he seemed just expiring, being pulseless and cold, but gradually revived by the liberal administration of hot brandy and water, and before 1 in the morning was much in his usual state. He got some refreshing sleep, and was as well as usual the next day. Three or four similar fits occurred in the course of this month.

On December 2d he was sent out to get the air, as the day was mild, and he had not been out of the house for three weeks. Just when crossing the street he brought up a mouthful or two of blood, and his nurse ran in with him. I arrived in a few minutes, and found him faint, with his face still bloody. A little cold water was given him, and he revived. He then fell asleep, apparently from exhaustion, and slept for an hour and a half. About 4 p.m. half a tea-cupful was brought up, and some of it, which had been caught in a basin, was shown me, and was fluid, and intimately mixed with minute bubbles of air, so that I made up my mind that it was from the lungs. After it came away he appeared relieved, and lighter. About 3 a.m. of the 3d, I was called up, his nurse saying he was going to bring up more blood. He seemed hawking something in his throat, and blood appeared at his nostrils; a little was spit up, and more seemed to be swallowed. This was no doubt the reason why I was told at first that he had vomited the blood; probably he did so after he had swallowed it. In the forenoon of the following day he was quite lively.

December 4th.—This morning he did not appear to be so well as usual, being more oppressed and blue. At twenty minutes to 3 in the afternoon his mother brought him to me, saying she feared he was going to take another fit. He was very livid; his lips, and

the point of his nose, and his fingers in their whole length, were absolutely blue. He was crying violently, as feeling much oppressed. He held out his arms to me, and I took him; and then he did the same to his mother. Immediately afterwards he became insensible, without any convulsion; the blue colour disappeared, and he became quite pale; his pulse sunk to 48, and his breathing to 10, in the minute; and at five minutes past 3 he expired; this last fit having lasted just twenty-five minutes. He was fifteen months old the day he died.

Inspection.—December 7th.—He was opened by Dr. J. G. Fleming, in the presence of Dr. Wilson and myself. The lungs appeared quite healthy, and without any engorgement. The moment the pericardium was opened, it was obvious what was wrong. The aorta was seen rising from the middle of the heart, and appearing more prominent than usual, because not overlapped by the pulmonary artery, which was less in size than a writing-quill. The heart and lungs were removed together.

The heart was gorged with blood; the auricles were opened from behind; the foramen ovale was open, and about three-eighths of an inch in diameter; the aorta was about a third larger than usual in a child of his size, and took its origin equally from both ventricles; it had the usual three valves at its commencement. The ductus arteriosus was open, scarcely larger than a crow-quill. From where it joined the pulmonary artery, the latter divided into its right and left branches; but its trunk was little larger than a crow-quill, back to near the right ventricle, where it was quite impervious.

The apex of the heart was next cut off, when the two ventricles were seen to be of equal thickness. The handle of the scalpel passed from each of them into the aorta. The septum was deficient, just at the root of the aorta, presenting a smooth concave border, leaving an opening through which the forefinger could be passed. The mitral and tricuspid valves were normal. The upper angle of the right ventricle was directed as usual to the pulmonary artery; but there was no opening, nor were there any traces of valves. The other viscera appeared natural.

The course of the circulation must

here have been very uncommon, inasmuch as the blood must have passed in a retrograde direction through the ductus arteriosus, that being the only way in which any *could* get to the lungs, as the root of the pulmonary artery was closed. The blood from the system, poured from the venæ cavæ into the right auricle, and that from the lungs into the left, from the pulmonary veins, must have mingled freely in their passage simultaneously into the aorta: besides that, a portion of the contents of the right auricle must have passed directly into the left, to help to fill it, the quantity which had come through the lungs having been very small indeed. It was no wonder that the poor little fellow should have been blue, as a mixture of three-fourths or four-fifths of venous blood, with but one-fourth or fifth of arterial, was the fluid supplied for his general circulation.

The little sufferer received temporary relief from hot brandy and water, of which he became very fond; also from a mixture containing ether and ammonia; and for six weeks before his death he suffered a good deal from cough, which was somewhat relieved by a mixture of mucilage and the camphorated tincture of opium. His intellect was always clear and lively. About the month of July he was able to stand at a chair; but after the fits came on he never attempted to set his feet to the ground. Dr. Wilson was extremely kind in seeing him, and suggesting remedies to relieve him; but a cure was too plainly out of the question.

ASIATIC CHOLERA.

To the Editor of the Medical Gazette.

SIR,

A FEW days since I was called to a case which presented all the symptoms of the true Asiatic cholera in a much milder form than the cases I saw at Oxford during the epidemic of 1831. Since that time several cases of Asiatic cholera have been reported in the medical journals as occurring sporadically during the prevalence of the common English cholera. This would seem to render it probable that such sporadic cases may have passed unnoticed before the dreadful epidemic to which I have referred, and that the Asiatic cholera itself may be nothing more than an

aggravated form of the disease so long familiar to us. The chief difference between the two seems to be, that, in the former, the bile and other secretions are suppressed; while, in the latter, they still flow. This arises, I conceive, from the blood being drained of its fluid parts much more rapidly in Asiatic than in English cholera.

In common diarrhœa, as well as in English cholera, the stools consist of the watery part of the blood, holding some small proportion of albumen in solution. Suppose this drained away with great rapidity, the blood would not be in a state to circulate freely through the glands, and, consequently, their secretions would be suppressed. Aggravate this state, and you will have not merely water holding albumen and salts in solution, but the liquor sanguinis itself thrown out, and hence the flakes in the watery motions of Asiatic cholera. It might thus, perhaps, be inferred that the same causes that bring about our common cholera, may, when acting with greater intensity, give rise to the more severe disease. The lividity of the countenance is produced in the same manner as the suppression of the secretions; for, as Dr. Stevens has proved, when blood is deprived of its serum, and, with it, its saline constituents, arterIALIZATION cannot take place; the whole of the blood in the arteries, as well as the veins, is dark-coloured; and this dark-coloured blood, circulating in the capillaries, gives a livid tinge to the countenance. As the blood is rendered thicker, and, at the same time, cannot obtain its proper quantity of oxygen (from the absence of its saline constituents), the heat of the body is lessened; the heart, not receiving its proper stimulus, beats faintly; and hence the coldness of the surface, and the weakness or absence of the pulse.

According to an analysis of cholera stools by Wittstock, of Berlin, they consist of:—

Water	1956.0
Chloride of sodium, with a few parts of chloride of potassium	6.0
Albumen, with phosphate of lime	7.0
Carbonate of soda, phosphate of soda, hydrochlorate of ammonia, salts, with organic acids, traces of uric acid, and osmazome	5.0
	2000.0

The most remarkable part of this analysis is the presence of uric acid; and it proves, if correct, that that substance, instead of being separated from the blood by the kidneys, flows with the fluid portion of the blood, which holds it in solution, into the intestines. It also assists in proving that the function of the glandular organs is merely that of separating from the blood substances previously contained in it. I am not aware that suppression of urine has been noticed either in severe diarrhoea or English cholera: but this is a point which deserves investigation. I shall now proceed to detail the case.

Sept. 7th.—I was called at 6 A.M. to see a girl, aged 10, the daughter of a labourer in this town, who had been attacked about 12 P.M. with severe vomiting and purging. She had complained of sickness the preceding day. She had eaten fruit two days before; but merely an apple yesterday. The general aspect of the countenance was anxious; the eyes sunk, with a livid circle surrounding them; the cheeks also were very slightly livid; the surface was cold, particularly the hands and feet; the pulse rather quick, but very small and weak. There was constant nausea, frequent vomiting of a colourless watery fluid, and the motions flowed away in the bed. The motions, as shewn by the sheets, were colourless, with a faint and not particularly disagreeable odour, and a fibrinous flaky substance was left on the sheet: in short, they were exactly such as I had seen in the cases of 1831. Cramps of the legs and abdominal muscles frequently occurred; and there was distressing thirst, the patient constantly calling for cold water.

I ordered her a tea-spoonful of brandy every quarter of an hour, and a mixture of creta with opium.

8 A.M.—Vomiting and purging of the same fluid continue. She has rejected each dose of the mixture. The cramps have somewhat diminished. The other symptoms as at the last visit. Ordered,

Hydr. Submur. Opii Pulv. aa. gr. ii.;
Glycerrhiz. Pulv. gr. xv. ft. pil. xij.
cap. j. om. semihora.

Continue the brandy. Allowed to drink as much cold water as she likes.

2 P.M.—Vomiting continues after taking any thing; pulse 100, weak; great thirst; bowels not so much re-

laxed, but the motions contain no trace of bile; tongue cool, but clean.

To continue the pills; to take a tea-spoonful of brandy every hour, and have a bottle of hot water applied to the feet.

10 P.M.—The skin warmer; pulse 100; cramps have been rather severe; thirst and other symptoms much the same, but the bowels have scarcely moved. No urine has passed since the commencement of the attack.

To continue the brandy and pills.

8th, 9 A.M.—Reaction complete; the skin hot; the pulse quick; the face flushed; tongue dry and red; bowels not moved since yesterday; vomiting ceased; the eyes much injected. The ignorant mother of the girl has given her half a pint of brandy since yesterday morning, and rather overdosed her. The indications appeared to be, to moderate the reaction, to move the bowels, and at the same time prevent any return of the vomiting. For this purpose I ordered the following mixture:—

R Potass. Nitrat. ʒj.; Magnes. Sulph.
ʒvj.; Acid. Hydrocyan. Dil. ℥xij.;
Aqua, ʒvj. Cap. c. j. amp. 2dis horis.

3 P.M.—The injection of the eyes has disappeared, but the face is still flushed, and of a brighter colour. The pulse has sunk to 86, and there has been no recurrence of the vomiting: the bowels not yet moved.

Cont. Mistura.

9 P.M.—Going on well, but no motion.

Pulv. Jalap. gr. v. statim.

9th, 9 A.M.—The bowels have been relieved three times; motions yellow; pulse 76; some griping pains in the abdomen.

Cont. Mistura.

8 P.M.—Pulse 70; countenance rather flushed; tongue clean and moist; no sickness; bowels relieved twice since last night; motions yellow. Is now asleep.

10th.—Convalescent.

I think all will agree with me in considering this a case of Asiatic cholera; or, which is the same thing, a case presenting every distinguishing feature of that disease.—I am, sir,

Your obedient servant,

PHILIP B. AYRES, M.D.

Thame, Sept. 12, 1842.

REMARKABLE CONSTIPATION.

Inability to empty the Bowels during Three Years.

By JAMES CHALMERS, Surgeon,
Cape of Good Hope.

(*For the Medical Gazette.*)

S. C. æt. 20. It appears that she has been troubled with constipated bowels ever since her birth. Her mother states that she never knew her to have a stool without the use of a piece of soap introduced into the rectum. At the period of puberty, menstruation occurred imperfectly: she was about 16 years of age, of a pale complexion, and of sedentary habits. Pil. Aloes. c. Myrrh. with Ferri Sulph. were prescribed.

Previous to the commencement of our history, her bowels acted imperfectly, and menstruation was irregular; in March 1839, the following is the note made.

This case now assumes an interesting character: she has not had a stool for 10 days; there is no fever, pain, or sickness, present. Purgative medicines of every kind have been given. On the 7th March, after fruitless attempts with the common enema syringe, a tube (similar to that recommended by Dr. O'Beirne in his work on Defecation) was gently introduced, and pushed up—pumping a little soap and water at intervals—until it reached 14 inches at least. Infusion of Senna was then pumped up till the abdomen was distended. In a few minutes, one or two pieces of scybalous matter, flattened, pale, yellow, and of faint smell, were passed. Her appetite is very bad; has never any desire to eat ordinary food; for days, merely picks a little at the breakfast-table, or eats walnuts or raisins, or an orange, and seems thirsty. Tongue white; papillæ large; gums spongy; pulse 90, small, weak; skin dry and harsh,

On the 8th, 9th, 11th, and 14th, the same means were used, but unsuccessfully. On the 15th, the tube was again used with a more favourable effect; $\frac{1}{2}$ lb. of fæces came away in small scybalous flattened, masses, from which considerable relief was experienced. There appears to be an obstruction a little above the sigmoid flexure of the colon; the tube is generally checked

in its progress, and on withdrawing it, it is always firmly grasped, as if spasmodic action existed in that portion of the bowel.

Quinine and rhubarb have been daily administered, leeches to the groins, and cupping-glasses to spine when the menstrual period was anticipated, or when spinal irritation existed.

In August, I had an opportunity of using a powerful electro-magnetic apparatus once or twice, which, on one occasion, had a favourable influence in causing spontaneous action of bowels. The pulse was much accelerated, and considerable excitement was produced during the continuance of the passage of the electro-magnetic current, which was applied to the epigastric region and spinal column. She was attacked with the prevailing epidemic (rubeola) and had it mildly: cough was the most urgent symptom, and remained for some months afterwards, but had more of a spasmodic or sympathetic than inflammatory character. Her rest is bad, and spirits have been, at times, much depressed. Every remedial means have been resorted to. Croton oil had a fair trial, both internally and externally, but without any effect; vomiting was produced when large doses were administered.

October 1840.—The case has continued the same for some months back, the bowels never having been relieved but by artificial means. Tonic medicines in great variety have been administered—Carbonate of Iron, Tinct. Ferri Mur., Iodine, Strychnine, in combination with bitter purgative extracts, horse exercise, shower-baths, sponging with the nitro-muriatic lotion, frictions on spine and abdomen, &c. After the use of the nitro-muriatic acid, the skin became highly tinged with bile, the linen stained by the cutaneous perspiration, and the urine was loaded; all the symptoms of icterus, except nausea and vomiting, were present. The total want of appetite for natural food at times still continues, and her existence is a wonder to every one, taking so little nourishment as she does.

During the month of December 1839, January, February, March, and April 1840, she had only two evacuations by the usual means. My accidental absence was partly the reason of so long a period passing without an evacuation;

she suffered very much during part of the period mentioned, but she is daily enabled to take exercise, and to continue her domestic amusements.

May 1841.—The fœces passed now on using the tube have a stronger smell and more natural appearance. The obstruction in the bowels does not seem so decided; a torpor exists, and there is a narrowing of the anus, but on introducing the finger per rectum, to examine its condition, when withdrawn it is covered by fœces.

April 1842.—Matters continue much the same as before; no evacuation without artificial means once in four, five, or eight weeks; the health is failing, and the internal organs begin to sympathise as her years increase; leucorrhœa has been more or less present for some months, although checked by lytta; her lips are not feverish; the abdomen tumid; the neck of uterus enlarged; pain almost constant in the back; the appetite not improved. A material diminution of bodily strength, and disinclination for exercise, have latterly shown themselves.

ON THE CIRCULATION OF THE LIVER.

To the Editor of the Medical Gazette.

SIR,

A FEW weeks ago a letter appeared in your journal from Dr. Carson, junior, in which he pointed out that I had been anticipated in publishing certain views concerning the circulation of the liver, which I conceived to be novel*. The views alluded to related to the question—Why the *venæ cavæ hepaticæ* should be formed in such a peculiar manner, as compared with the veins generally, as to resist compression, and preserve their walls patulous, instead of collapsing. The explanation which I offered was to the effect—that this structure allowed the blood in the hepatic veins to come under the influence of atmospheric pressure, so as to be accelerated in its course to the heart by that means: and that the auxiliary force thus brought in aid of the other powers circulating the blood, relieved, in a secondary manner, the vessels of the portal system. It having been shown by former inquirers, that when the chest

is expanded during the act of inspiration, there is a tendency for a vacuum to be formed in the cavity of the pericardium, and that the blood, urged onwards by the weight of the atmosphere to occupy that space, rushes along the veins with increased velocity at that time, there being a special provision to prevent the main trunks from collapsing when the pressure is so directed upon them, I was led to conclude that the rigid structure of the veins of the liver was intended to allow the blood to flow from the gland into the heart, under the same power of compression, with an accelerated rate of motion, and without their undergoing any diminution of their calibres. Some remarkable peculiarities in the relative situation of the hepatic veins to the right auricle, particularly as influenced by the successive movements of the diaphragm in respiration, seemed to corroborate that view.

It is my duty to mention that, before composing the paper which contained these observations, I had consulted with considerable diligence all the recent standard works on physiology, as well as other treatises where I thought the same subject would be discussed, so as to be assured that they had not occurred previously to others. But I did not find any thing bearing on my inquiries; indeed, the particular anatomical structure of the hepatic veins adverted to, did not seem to have been thought of before as a problem which required solution.

Dr. Carson has, however, shown, in a way preventing all dispute, that the principal part of the views which I advanced had suggested themselves several years ago to M. Berard, professor of physiology in the school of medicine at Paris; and at a later period, to his own distinguished father; and that the former had propounded them in a memoir published in the *Archives Générales de Médecine*; while the latter published them in the third edition of his *Treatise on the Circulation of the Blood*. I cannot do otherwise, therefore, than relinquish my claims of priority for these views to those gentlemen; and I only venture to hope that, having been introduced again by an independent course of observation and reasoning to the notice of physiologists, the opinions in question may be thought deserving of greater atten-

* See the *MED. GAZETTE* for July.

tion, in future, than has hitherto been directed to them.

I take this opportunity of laying before your readers some particulars of a case which has recently come under my observation, and which may be interesting from the appearances found in the liver, after death, in connection with an unusual and remarkable condition of the pericardium and diaphragm, throwing light on the question touched upon above.

I made the dissection to-day of a female, named Stallard, æt. 39, who has been under my care in the Cancer ward of the Middlesex Hospital for the last eight months. She suffered during that time from open cancer of the left breast, and had besides numerous scirrhus tumors, mostly of a small size, situated in different parts of the body. The cancerous ulceration of the left breast spread superficially; and all around it, from the clavicle to the lower margin of the chest, and from the sternum to the axilla, the skin and muscles were converted into a thick, nodulated mass of scirrhus substance, adherent to the ribs. When first admitted, the patient was observed to speak with a feeble interrupted voice, which became worse latterly; but it was not until a month before her death that her breathing became considerably oppressed. She then presented the symptoms of labouring under hydrothorax; and her feet and ankles swelled. She died greatly emaciated, worn out from the combined effects of dyspnœa and the extensive cancerous disease. My attention had not been drawn during her life-time to the condition of the alvine evacuations, further than to be informed that she was generally constipated. Upon questioning the nurse afterwards, it appeared that the faces had been commonly dark, without having any traces of blood mixed with them.

In describing the post-mortem examination, I need only advert to the points of interest in connection with the circulation of the liver. When the ribs had been sawn through, it was found necessary, before they could be lifted from the left side, to use the knife, in order to separate them from the lungs, to which they adhered. The cancerous structure of the exterior passed through the ribs and their cartilages, and involved the lung of the same side at its anterior and lower

parts. Upon exposing the right side of the chest, a large quantity of dropsical fluid escaped; and the lung, which was studded over its surface with numerous small scirrhus tumors, was collapsed, so as to have lost, as well as could be computed, about one-eighth of its natural bulk; otherwise, this lung, and the superior portion of that of the left side, appeared natural. At this stage of the dissection the appearance of the pericardium, which had been unavoidably opened in removing the sternum and ribs, presented a singular character. The heart itself was of average dimensions, and healthy; but the pericardium did not collapse as usual, so as to close upon the heart. Its walls were found to be rigid, and the sac had the appearance of a hollow case or basin, formed of solid material. The explanation of this peculiarity was soon apparent. It has been stated that the morbid structure affecting the exterior of the chest extended to the left lung, and converted its anterior and lower parts into the same kind of growth. On further examination, it was found that the disease had been communicated to the diaphragm also; and that the whole of the left side of this important muscle, from the margins of the chest to the spine, and reaching to the mesial line, was incorporated with the diseased lung, and converted into a scirrhus, nodular mass, quite immovable. It was accordingly owing to all the parts surrounding the pericardium having become involved in the malignant structure, and to that membrane adhering to them, that the walls of the cavity preserved their natural shape, without collapsing.

Directed by this appearance of the pericardium, and from considering that it must have been incapable, during life, owing to the change in its structure, to undergo those varieties in its relative dimensions which take place in respiration, and on which depend the differences in the velocity of the blood in the veins observed in connection with breathing, I looked with increased interest to the condition of the liver and its blood-vessels. The gland was free from any scirrhus tumors; and the orifice in the diaphragm for the transmission of the vena cava inferior was of its natural size. On the upper convex surface of the liver no remarka-

ble appearance was visible ; but, for an inch along the whole of the sharp anterior border, the colour of the gland was changed to a dark-greenish purple. Having raised the liver, so as to present its inferior surface to view, the same dark colour was observed to extend over every part of this surface ; but, instead of its being of a greenish-purple, it approached more nearly to jet-black. The same kind of appearance is not unfrequently met with in the more depending parts of the liver, owing to the blood gravitating after death to the under surface : but, in all my experience of post-mortem examinations, I do not remember to have seen the discolouration of the gland at once so deep and so extensively diffused as in this dissection. Again, looking to the veins of the abdomen which form the trunk of the vena portæ, they were congested in a remarkable manner ; in the mesentery more especially, the crowding of the numerous enlarged and dark-coloured trunks was such, that the membrane seemed to consist almost entirely of a thick tissue of veins. The intestines also partook of the deep colour produced by the congested state of these vessels.

In reflecting on this case, I cannot but connect together, as cause and effect, the change which has been described in the structure of the pericardium, with the congestion of the liver and of the veins of the viscera. It appears that, in consequence of the rigid state of the walls of the pericardium, this sac was prevented from undergoing those changes in its capacity which take place naturally in the successive acts of respiration : accordingly, that dilatation of its cavity during the act of inspiration, on which the operation of the peculiar power of suction, which has been shewn to come in aid of the common forces circulating the blood in the liver, depends, could not be produced : whence the blood, deprived of the assistance of this auxiliary force, was delayed in the gland, and, in a secondary manner, obstructed the flow of that in the veins of the viscera.

It will, perhaps, be objected to this explanation, that there is no necessity to have recourse to such an unusual cause as that which I have pointed out to account for appearances which are by no means uncommon. It may be said that the difficulty of breathing, from which the patient suffered for

some time previously to her death, was enough to explain the loaded state of the blood-vessels observed in the liver : for every pathologist is acquainted with the fact, that it is a frequent thing to find this gland congested in cases where the respiration is impeded. But it must be observed, on the other hand, that, in cases where the blood is preternaturally accumulated in the liver owing to difficult respiration, the congestion is general ; and it is exhibited most strikingly in the heart and lungs. Indeed, the commonly received explanation of the liver being congested in such cases is, that the blood cannot make its way freely out of the gland in consequence of its being collected in the lungs and heart to such a degree as to prevent the admission of any further quantity into the chest. Now, in the present case, the congestion was certainly not general. It was particularly observed, that neither the heart nor the lungs were in that condition. On the contrary, the heart was of moderate size, and contained only the average quantity of coagulated blood ; while the lungs, more particularly the right, were rather pale, and of small specific gravity, than otherwise. In short, the partial nature of the congestion—its being confined so manifestly to the hepatic circulation—was the principal circumstance in the dissection which led me to conclude that the cause was of a specific kind—such as that which I have pointed out—and not a general one.—I am, sir,

Your obedient servant,

ALEXANDER SHAW.

23, Henrietta Street, Cavendish Square,
Sept. 1842.

CASES OF

ACUTE HYDROCEPHALUS

TREATED BY HYDRIODATE OF POTASS.

—

To the Editor of the Medical Gazette.

SIR,

I TRUST you will find space in some early number of your valuable periodical for the insertion of the following brief history of three cases of acute hydrocephalus, in which hydriodate of potass was found decidedly useful. Perhaps this medicine has been administered by other persons in the same disease—most likely it has in the chronic form, but I do not recollect to have

seen any account of its exhibition in these cases in any of the medical journals, or elsewhere. Each succeeding day that I live, I see more and more cause for disapprobation of what is called routine practice, more especially, indeed, as regards the abstraction of blood and the use of purgative medicines, by which proceedings I am convinced a great many of our fellow-creatures are consigned to an earlier grave than might have awaited them, but for these means misapplied. Witness, for instance, the indiscriminate use of the lancet in apoplectic and paralytic seizures, as admirably alluded to in a late publication by Dr. Holland, in the chapter on those subjects. With me, sir, the opinion is grounded on nearly twenty years' experience, and I suspect that the observation will apply even more closely to children of tender years than to adults. Helpless, and unable to express clearly their own feelings, wishes, or opinions, should they have any, they are the easier victims of the routine I have alluded to. In no disease is venesection more generally misused than in the hydrocephalus of children, though the remedy, practised with decision, is of the highest efficacy in the onset of the acute form. The disease, however, is very often of mixed character—very often complicated with some serofulous degeneration, as is admitted by Golis, Cheyne, Forney, and others; and these facts should surely make the routine practitioners somewhat more cautious in the practice of blood-letting than they usually are. Moreover, bleeding in the advanced stages of the disease, the excessive smearing with mercurial ointment, together with the reckless exhibition of calomel to the last hour of life, are measures of very questionable utility, and by no means, as some author says of digitalis, likely even "to soften the pillow of death." But without further prelude, sir, allow me to state that 17 or 18 months ago, two cases of acute hydrocephalus, in children about a year old, were in progress of treatment, by my partner, Mr. Chinery. He had had recourse to bleeding with moderation—so with mercurials and other remedies proportioned to the strength and powers of the little patients, and the whole of the treatment had been conducted on rational principles. The gums had been freely scarified, though there was no

evidence that the cerebral irritation was immediately connected with dentition. One of the children had rather a large head, and might have been the subject of some chronic disease on which inflammatory action had supervened, and the child was certainly of a serofulous diathesis; not so with the other. It was previously healthy, born of healthy parents, had gone through the usual symptoms described by authors as appertaining to acute hydrocephalus, and had been treated accordingly; but despite of all measures was apparently in a dying condition. The mother, though fondly attached to her child, was exceedingly averse, conceiving its entire inutility, to making any further trial of medicine; and I should say that medicine of any kind was only got into the stomach by putting it far back on the tongue, and depressing the organ till deglutition was unavoidably accomplished. This child, in addition to strabismus, laboured respiration, convulsions, and other symptoms, supposed by some to be indicative of effusion, had for several days together complete opisthotonos, the body being stiffly arched from the occiput to the ossa calcium. Both children were occasionally convulsed, comatose, and miserable for days together, and in this condition I suggested a trial of the hydriodate of potass, in half grain-doses, every two or three hours. The only visible effect of this, in connection with the rapid improvement of both children, was considerable diuresis, and in one, much saliva dribbled from the mouth. Both recovered perfectly and speedily, and are living and healthy at this time.

An equally well-marked case has occurred to me more recently. On the 10th of May last, I visited the infant child of a small farmer, on the borders of the New Forest. The child, about 14 months old, robust and previously healthy, exhibited the usual symptoms of pyrexia. Considering that dentition might be the source of irritation I lanced the gums freely, and as the bowels were costive, directed a purge of calomel and jalap. The next day the child had become more feverish, occasionally screaming, and exhibiting annoyance at light. The tongue and breath were foul; the pulse quick and varying; the countenance flushed; and the scalp very hot. Leeches were applied to the temples and a cold lotion to

the head, and in the evening, the respiration being laboured, and the more especially as crepitation was observed over the right lung, four leeches were applied below the clavicle, a nauseating mixture was prescribed, and the calomel purge repeated. After this the breathing was somewhat better, but the febrile symptoms continued. On the 12th and 13th, the child remained in very much the same state, but nearly insensible to objects around it. The bowels obstinately costive; the evacuations that were sparingly obtained from them by different medicines were of a dark colour. A blister was applied to the nape of the neck, calomel was administered every four or five hours, and a mixture of nitre and acetate of ammonia.

On the 14th, extreme stupor seemed to overwhelm the child; the pulse, which throughout had been very quick, became more irregular and indistinct, and a clammy sweat overspread the body.

On the 15th, the pupils were dilated and immoveable, and insensible to light. There was complete paralysis of the right side, while the limbs of the left were in constant tremulous motion, the hand being frequently drawn to the head with an undulatory automatic movement. This state of things continued to the 18th, with occasional convulsions and almost entire insensibility. Wine had been administered without benefit, and I do not know how it was that I did not prescribe the hydriodate of potass a day or two earlier, for the effects of that medicine, in the two cases before alluded to, had made a considerable impression on my mind at the time. Without much expectation of doing good in this case, I prescribed the medicine as before, and with precisely the same results; not indeed instantaneous, but as an observant grandmother remarked, it appeared to improve with each dose of the medicine; the only appreciable effects being a speedy diuresis and dribbling of saliva.

I do not purpose attempting an explanation of the *modus operandi* of the hydriodate of potass in these cases. To this day, sir, pathologists are not agreed about the disease in question. I suppose it is admitted on all hands that water is not the disease; but the character of the inflammation, even

whether it be in all cases inflammation at all, or venous engorgement, or ramollissement, or debility, seems to be matter of difference. The symptomatology, too, is obscure. The best authorities, Abercrombie, and others, admit that they cannot make a sure diagnosis between meningitis and inflammation of the cerebral substance. Again, the so-called signs of effusion, though enumerated so elaborately by Golis and many of the older writers, sometimes exists without any effusion at all, and therefore are in no way diagnostic. In short, much uncertainty prevails. Whether the hydriodate of potass was beneficial in these cases by revulsion, as an evacuant, or by aiding the absorbents, (for their existence within the cranium is I believe allowed), I know not: or was it by goading into action the mercury which had been previously taken? Some have fancied such a process, and it is worthy of note that, in two of these cases, salivation occurred. The utility of the hydriodate in various diseases, cutaneous, rheumatic, dropsical, and others, is well known to most practical men; but its administration in these hydrocephalic instances is, I believe, new; and I would only call the attention of your readers to the fact, that in a state in which the most characteristic symptoms of the last stage of acute hydrocephalus were present, the aforesaid effects were produced, and death was apparently frustrated. The symptoms disappeared. In each case the disease gave way just in like manner as the autumnal forest mist is dispersed by the morning sun, and the little patients most unexpectedly recovered. If, in the hands of other medical practitioners, in cases of acute hydrocephalus, where bleeding and the usual remedies have been judiciously had recourse to in the early stage, unavailingly, similar effects to those here narrated should be noticed on a trial of the hydriodate of potass in the latter stage of the disease, I feel assured that the pages of the *MEDICAL GAZETTE* will ever offer a ready channel of communication on so important a subject.—I remain, sir,

Your obedient servant,

CHARLES FLUDER.

Lymington, Hants,

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medice tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO

HINTS TO PUPILS.

THERE is a well-known adage which asserts that the by-stander sees more of the game than the players. This is an exaggeration; yet it is certain that he sees many points which they overlook. Now, life is a kind of game, as Dr. Franklin observes, and the rule is applicable to its struggles. Hence, no part of our duty has ever appeared to us more useful than the addressing a few words of advice to young medical students; embarked, as they frequently are, on the troubled ocean of London life, with scarce a friend to aid them in its navigation.

The first error which the student often commits is the parent of a hundred more. We mean the mistake of leading an isolated life in lodgings, instead of becoming an integral part of a family, if it be at all in his power to do so. It is so obvious to every man of penetration, that a solitary existence blunts the feelings, without sharpening the intellect, and offers a cloak for every irregularity and every form of idleness, that we cannot express ourselves too strongly against it.

If, indeed, an abode can be selected for the student, where the head of the family is a man both of probity and talent; where domestic happiness is the pledge of sound principles, and professional success of professional knowledge; where instruction is not dry, nor relaxation coarse, it would be difficult to suppose that the most careless father would hesitate to confer such a boon upon his son. But if so golden an opportunity does not present itself, lesser

advantages are not to be scorned. Without shining talent, a man may yet be a useful guardian; and even the humblest roof, when pillared by sobriety and good temper, may afford a creditable asylum. In short, any decent family must be better than a mere lodging-house. The great modern painter of London life, in its less elegant phases, has scarcely exaggerated either the habits or the dialect prevalent in some of these unfit receptacles for medical pupils.

The next point is to select a good medical school; and here an impartial friend would be of infinite advantage. He would warn the beginner against all schools whose sole merit is the lowness of their terms, or the facility with which certificates are granted.

Nor is it a slight objection to a school, that the most practical branches of our art are taught there by men of no great practical reputation. The ambitious student will naturally seek the best schools, when he is informed how frequently the mantle of an eminent teacher has fallen upon his disciples; so that medical fame seems to have descended from one generation to another, not by the accident of birth, but by the elective affinity of genius. By the regulations of the Society of Apothecaries, the student, during his first winter session, must attend a hundred lectures on chemistry, and a hundred on materia medica and therapeutics; and since "the number of lectures on anatomy and physiology, and of anatomical demonstrations, must be in conformity with the regulations of the Royal College of Surgeons of London, on these subjects," there will be, at least, 140 of the former, and 100 of the latter. This makes 440 lectures, or an average of about three a day; and if he should happen to dissect, and attend the surgical practice of an hospital, during the same period, his time will

be most fully occupied. For, in addition to the seven or eight hours a day spent in this manner, several will be taken up in reading over his notes of lectures, and referring to his text-books for further information. It is plain that the best lectures are merely a summary of the subjects on which they treat, and that it is, consequently, an important part of the lecturer's office to refer his auditors to the best monographs and systematic treatises. So diligent a course of study, however, is easier on paper than in reality. Too often it happens that the student, accustomed to little save the easy details of practical pharmacy, sinks under the heavy load, or, in truth, has not even energy enough to attempt to sustain it. It is certainly difficult to arrange a plan for the simultaneous pursuit of so many studies without clashing; but a Gordian knot, hard to untie, is often easy to cut, and the process is sometimes applied to lectures and hospital attendance. Now, one of the advantages which must result from the residence of the student in a quiet professional family is, that this wholesale avoidance of every object for which he came to town can hardly take place. The head of the family, who will not consider himself as the mere keeper of a boarding-house, but as the guardian and teacher of the students confided to his care, can easily ascertain whether their attendance on lectures is gradually sinking into a merely nominal one, or whether their diligence is as great as their strength and capacity will allow. Such a man will lighten their toils by those hints which are better imparted in familiar conversation than in formal discourses—thus contributing to bring their studies within the limits of possibility. He will warn them that, for the present, their attention must be directed solely to professional pursuits; and that mere

science or literature, however attractive, must be placed in the background:—

All superfluous branches
We lop away, that bearing boughs may live.

Even chemistry, therefore, must be restrained within certain limits, particularly by those students who are confined to the minimum of time indicated by the Worshipful Society. Those who can extend their studies over a longer period than three winter and two summer sessions, will find it highly profitable to do so. The Apothecaries' Regulations ordain that this may be done, "provided the lectures and medical practice are attended in the prescribed order, and in the required sessions." In the prescribed order they may certainly be attended; but if spread over a longer period, how can they all be attended in the required sessions? The Regulations contain another apparent contradiction. It is stated, at one place, that the attendance of the student is required at an hospital for eighteen months; but, at another, the choice is given him to attend twelve months at an hospital, and six at a dispensary. Those who are cramped for time should attend for the short period of eighteen months at an hospital; while those who are not so limited, and who desire to learn the practice of physic in all its varieties, should attend a dispensary likewise, where they will find that the general run of cases, and the relations of the patients, bear a greater resemblance to ordinary private practice.

Our readers will have observed that St. Luke's Hospital has lately been thrown open to pupils, with the restriction, that no one shall be admitted who has not studied his profession for four years, or attended the medical practice of an hospital for eighteen months. In most cases, we should think the best time for making use of

this privilege would be after the pupil has passed the Hall and College, and is seeking the means of completing his professional education. He will find a sound knowledge of the varied forms of insanity of the highest utility in his medical career. Most practitioners have hitherto had few or no opportunities of acquiring this, and it is a very important addition to the treasures of knowledge offered to the next generation.

It is to be hoped that improvement will not stop here, but that the Fever, the Small-pox, and Lying-in Hospitals, those comparatively sealed deposits of inestimable information, may likewise hear the "Open, Sesame!" of reform.

One word more. We would strongly recommend each and every student to try his chance for the prizes so liberally offered at almost all medical schools; yet, as the vanquished must be far more numerous than the victors, we would still more strongly urge the less successful not to despair. Another time they may be more fortunate; or, should this not be the case, let them be consoled by the reflection that unremitting diligence is certain to carry off some prizes in life. Though the gold and silver medal be borne away by more brilliant competitors, industry never fails of its reward. Let them not spurn what it bestows:—

*Non possis oculo quantum contendere Lynceus,
Non tamen idcirco contemnas lippus inungi;
Nec quia desperes invicti membra Glyconis,
Nodosâ corpus nolis prohibere chiragrâ.*

Hor. Ep. Lib. i. 1. 28.

We do not think it right to speak of individual schools; but for them refer to the advertisements on our wrapper; and we shall next week take leave of the subject by some general observations on medical education.

INSPECTORSHIP OF ANATOMY.

DR. SOMERVILLE has ceased to hold the appointment of Inspector of Ana-

tomy, and is to be replaced by Mr. Bacot and Mr. Rutherford Alcock.

We understand that considerable alterations are to be made in this department. The mere procuring of bodies, and their removal, are to be entrusted to subordinate officers, while the inspectors are to see that proper objects are procured—that the business of dissection is conducted with propriety—and that the remains are interred.

OUR VOLUMES FOR 1842-3.

THE arrangements which we have made for the ensuing volumes are such as, we think, will be creditable to the journal and satisfactory to our readers.

In our next number we shall give the first of a course of lectures on Midwifery and the Diseases of Women and Children, by Dr. Robert Lee; and, in a few weeks, commence a selection from the Physiological Lectures of Dr. Knox, of Edinburgh, which, but for unavoidable circumstances, should have appeared last year. It is also intended to give a short series of six or eight lectures on the Pathology of the Urine, by Dr. Golding Bird, and clinical observations from various quarters, beginning with those of Dr. Lawrie, of Glasgow.

DEATH OF DR. FRAMPTON.

WE have to announce the decease of Dr. Frampton, who died at his house at Hackney, on Wednesday, Sept. 21, 1842, in the 77th year of his age.

He was the eldest son of the Rev. Algeron Frampton, incumbent of the parish of Tokenham, in Wiltshire, and was born on the 7th of January, 1766. He received his early education at Marlborough, whence he proceeded to St. John's College, Cambridge, in the year 1783. His success at the University was most brilliant. He took the degree of Bachelor of Arts in 1787, and obtained the second place in the Tripos:

his fellow collegian and friend, the late Sir Joseph Littledale, being the senior wrangler of the year. He afterwards became a lecturer at, and subsequently fellow of, his College; and in due time filled the office of Moderator in the University.

In order to acquire a knowledge of medicine, he spent two years at the University of Edinburgh, and subsequently studied in London, first at St. Bartholomew's, afterwards at the London Hospitals. He took his degree of M.D. in 1797, and became Fellow of the College of Physicians; of which body he filled the office of Censor, and for many years before his death was one of the Elects.

In the year 1800 he succeeded the late Dr. Fox as one of the physicians to the London Hospital, which office he held for forty years, paying most unremitting attention to its duties; until about two years since, when his infirmities compelled him to resign.

He rapidly obtained an extensive private practice in and around the eastern parts of the metropolis; and at one time enjoyed an eminence not inferior to that of any of his contemporaries. He was one of the original members of the Medico-Chirurgical Society, but the engagements of a very active life prevented his becoming a contributor to its Transactions; and it is to be regretted that he did not find leisure to make known, through any other channel, the results of his ample experience.

For several years before his death he had been much afflicted by rheumatism and gout; and for the last two had laboured under enlargement of the prostate, which, for a time, occasioned retention of urine, and confined him to his bed, from which he never again rose; for though much relieved in this last complaint, his other infirmities had brought him to a very helpless condition. He retained his mental faculties and senses unimpaired to the last. A failure of appetite caused a rapid decline of strength, and gradually sinking, he closed a long life of activity and usefulness on the 21st of September, 1842, expiring almost without a struggle.

Dr. Frampton was an excellent practical

physician, and as such was highly esteemed by his professional brethren. He was mild and unassuming in his manners, kind and benevolent in disposition. He was beloved by his family, and highly valued by his friends, by whom his memory will long be cherished.

ANEURISM OF THE EXTERNAL ILIAC ARTERY—

LIGATURE OF THE VESSEL CLOSE TO THE BIFURCATION OF THE COMMON ILIAC ARTERY.

BY MR. BELLINGHAM.

MATTHEW DALY, aged thirty-two, a slender and healthy man (in other respects) was admitted into St. Vincent's Hospital August 18, 1842, under my care, labouring under aneurism of the external iliac artery on the right side. He has never suffered from any illness of consequence; had been in the habit of drinking, but has given it up for the last two years. He is a brush-maker by trade, and his occupation consists in constantly turning a lathe with the right foot. He continued to work until three or four days previous to his admission, under the impression "that the disease would wear away."

The aneurism is of about three months' duration. His attention was attracted to it by the swelling, which at that time (he says) pulsated strongly. It was, however, quite unattended by pain, and it has increased slowly in size. Recently, he has begun to suffer pain of a dull, aching kind in the part, which obliged him to give up work, and to seek admission into hospital. He has never received any injury in the part, or ever strained himself that he recollects.

The aneurismal tumor is about the size of a moderately-sized orange, but more oval in shape, seated above Poupart's ligament, and extending about half an inch below it. A very strong impulse is communicated to the hand placed on it, but no fremitus. Immediately below Poupart's ligament, however, there is a slight fremitus, and on applying the stethoscope a loud single bruit is heard. There is no swelling or œdema of the foot; the circulation is perfectly regular and tranquil, and the heart's action natural.

In consultation with Sir Philip Crampton and Mr. Cusack, it was determined to place a ligature upon the common iliac artery on the right side; as it was supposed there would not be found sufficient room between the aneurism and the division of the common iliac, the external iliac being

probably diseased above the aneurismal tumor.

A purgative draught was given on the night before the operation, and a cathartic enema administered the following morning, by which the bowels were well cleared out; an hour before the operation the patient took forty drops of laudanum.

The patient being placed on his back, slightly inclined to the sound side, having the thorax elevated, and the thigh bent up the pelvis, I commenced the operation (assisted by Sir Philip Crampton, Mr. Cusack, and Professor Porter) by a semi-circular incision, beginning on a line with the last rib, and terminating nearly opposite the anterior and superior spinous process of the ileum, and about an inch and a half internal to this process. Its length was about five inches, and the concavity towards the umbilicus; by this the integuments and superficial fascia were divided; the fibres of the external oblique muscle were then incised in the same direction, and next those of the internal oblique; by which the transversalis muscle was exposed. A cautious incision was made through the fibres of this muscle at the lower part of the wound, and a director endeavoured to be introduced under them. This muscle, however, was found to be considerably hypertrophied, being double or treble its natural thickness. On arriving at the transversalis fascia, it also was found to be increased considerably in thickness, and presented almost a tendinous character. A portion of it was raised with a forceps, and cautiously incised; a director was then introduced, and an incision made sufficient to admit the finger, upon which this fascia was divided by a probe-pointed bistoury, both upwards and downwards. No artery was divided in this part of the operation requiring a ligature; the bleeding appeared to be altogether venous.

The peritoneum was now very cautiously raised from the subjacent iliac muscle by insinuating the fingers behind it, and this proceeding appeared to give much more pain than was expected. As the peritonæum was detached, Mr. Porter, with his hand in the wound, drew this membrane and the intestines towards the opposite side; the separation of the peritoneum was continued until my finger reached the upper extremity of the external iliac artery; and the expected difficulty from the protrusion of the intestines was much less than had been anticipated. After a short time I succeeded in getting a view of the vessel, and, as it appeared to be perfectly healthy, its sheath was opened to a small extent by means of the blunt extremity of a director; and Mr. Trant's aneurism needle was then passed under the artery, from without inwards, without much difficulty; and here the ad-

vantage of his instrument was fully proved, for as soon as the eye of the needle appeared at the opposite side of the vessel, the ligature was drawn up by it, which, owing to the depth of the wound, and the distance of the artery from the surface, must have been attended with delay and difficulty, if the common aneurism needle had been employed. A single silk ligature was used, and as soon as it was tightened the pulsation in the aneurism ceased. The edges of the incision were then brought together by the interrupted suture and adhesive plaster; the patient was placed in bed, and took sixty drops of laudanum. The operation was completed in less than thirty-five minutes.

Eight o'clock P.M., reaction has completely set in; both lower extremities feel warmer than natural; he has a little thirst. Pulse eighty, and has had some sleep since the operation.

August 27th.—Slept well last night; no pain any where except in the wound; no tenderness on pressure over the abdomen; no sickness of stomach: some thirst; wishes for something to eat; pulse seventy-two; temperature of the ham, on right side eighty, on left ninety.

28th.—Did not rest quite so well last night; was annoyed by distension of the abdomen from flatulence, which occasionally gave him pain; pulse seventy-six; no thirst, nor pain on pressure over any part of the abdomen; the aneurismal tumor appears to be somewhat diminished in size.

29th.—Pulse seventy-two; slept comfortably last night; feels hungry, and wishes for some solid food; temperature of both limbs similar. The wound was dressed to-day; the lower portion has united by the first intention; water dressings and adhesive plaster applied; sutures not disturbed. As the bowels have not been moved since the operation, a little castor oil was directed to be administered immediately, and repeated at intervals, until it operated.

30th.—Bowels moved freely; feels more comfortable since; no tension or uneasiness in the abdomen; the aneurismal tumor appears to be more solid.

31st.—Wound suppurating freely; no thirst; appetite good; temperature of both limbs equal; pulse eighty. Ordered some weak chicken broth.

September 2nd.—He complained last night of pain over the middle sternal region, increased on inspiration. A mustard cataplasm was applied, and this morning the pain is much relieved; his pulse was slightly increased in frequency, about eighty-eight; in every other respect his condition is satisfactory.

5th.—The wound was dressed with charpie to-day; the discharge is abundant, and of a good quality; healthy granulations are

springing up from the bottom; the upper and lower portion of the incision have united by the first intention; pulse regular; no thirst; appetite good; has eaten chicken for his dinner the last two days.

8th.—The wound has contracted considerably, and the discharge is diminishing; he sleeps well, and says he has not felt so well since the operation; no pulsation can be felt in the femoral or anterior tibial artery; he eats mutton chop for dinner with appetite.

13th—19th day.—The aneurismal tumor within the last day or two has become painful when pressed about the centre, and its contents at this point are evidently more fluid than before; he also suffers from a feeling of distension in the part; otherwise he is in very good health, eats his breakfast and dinner with appetite, and has been allowed porter for some days. The ligature is not yet loose, and it gives him pain when it is gently pulled.

15th—21st day.—To-day the dressings were found to be deeply coloured with blood, and, on examination, a small orifice was detected at the inferior angle of the wound, through which a mixture of pus and blood could be squeezed. The aneurismal tumor is smaller and less tense, a portion of its contents having been evacuated in this way.

16th—22nd day.—The discharge of pus and blood continues, but in diminished quantity, and the aneurismal tumor is much smaller. The ligature was gently pulled to-day, when it yielded a little. This proceeding, however, caused, apparently, very great pain, which was referred to the hip.

17th.—A feeble pulsation detected to-day in the femoral artery high up in the hip; none in the anterior tibial.

18th—24th day.—The ligature came away this morning without any pain, and was not followed by the discharge of a drop of blood. The wound is very much diminished in size, having filled up by granulation nearly to level with the skin, except at the point where the ligature presented. His health is very good; he eats heartily, and sleeps well; the aneurismal swelling is diminished in size; but the integuments at one point covering it, are discoloured and thinned, and its contents at this part are very fluid.

FREDERIC'S HOSPITAL AT COPENHAGEN.

PROF. BAUG'S METHOD OF TREATING FEVER.

THE remedies which Professor Baug uses are as follows:—

1. *Pure fresh air.*—He takes care that a

continuous stream of fresh air shall surround the patients in their wards. Hence the windows are kept open immediately over the bed in which the patient lies on a mattress; at any rate as long as the violence of the fever requires this cooling method.

2. *Cold water.*—The heads of all the patients are covered with linen steeped in cold water; they are allowed to drink as much cold water as they like; and when stupor, fierce delirium, and other signs of congestion towards the head, predominate, the head is held over the edge of the bed, and several pitchers of cold water are poured over it. If the skin is very hot, affusion is sometimes employed over the whole body, but more usually it is merely washed with the cold water. If a dry skin is accompanied by nervous symptoms, tepid baths are prescribed, together with cold fomentations or affusions.

3. *Refrigerating and mucous beverages* alone are permitted.

4. *Emetics* are given, when vertigo and a bitter taste in the mouth occur together, and when they are not contra-indicated by real weakness, great stupor, or any local inflammation, particularly of the abdominal organs; but if these symptoms are present in a slight degree only, or have been mitigated by bleeding, the Professor finds emetics advantageous, and the more so, the sooner they are given.

5. *Venesection* is rarely employed, and only when important inflammatory congestions towards the nobler organs are present; in general, leeches only are used, or, when they are not to be had, cupping. If the cold affusions do not fulfil their object, or when general plethora threatens congestion towards some other organ, then, even if the head has become tolerably clear, six or eight leeches are applied twice or thrice to the temples; and if there are fixed pains, or a constant disturbance of function in any thoracic or abdominal organ, from ten to twenty leeches are applied in its neighbourhood.

6. *Sinapisms* are always applied to the soles of the feet; and blisters are often placed on the back of the neck, the chest, the abdomen, &c.

7. *Laxatives* are frequently prescribed. When the emetic has not purged at all, or but little, they are given on the following day, and repeated according to circumstances. Those usually selected are Epsom salts, or rhubarb with sal ammoniac, or from ten to twenty grains of calomel, or castor oil, or clysters.

8. *Mineral acids* are used in refrigerant drinks, to subdue either noxious secretions or septic (putrid) symptoms.

Of the remaining digestive remedies, nitre

and cream of tartar are prescribed, the latter either alone, or together with the former; more rarely a saturated solution of acetate of potash is given to check vomiting.

Cinchona, camphor, valerian, musk, ether, &c. are rarely required; they are indicated by septic and nervous symptoms, and then musk is the best remedy.

As to single symptoms, they are, of course, treated in various ways; against the majority, leeches and blisters are employed with advantage. Dangerous diarrhoeas are treated at the commencement with ten grains of calomel or with castor oil, first in larger, then in smaller doses, to assist the evacuation of injurious matter; afterwards with clysters of infusion of chamomile; and if the diarrhoea continues, and is accompanied by pain, it is treated with leeches. Blisters and tartar emetic ointment are often indicated. Of late, especially when the fever has been a real abdominal typhus, the Professor has given acetate of lead, combined with vegetable carbon, with good effect; the dose being half a grain of the former with five of the latter, and ten grains of starch, from four to six times a day. He has found the regular astringents more useful in the form of clysters, (*e. g.* two or three grains of opium) than when given by the mouth. The mucilage of gum arabic with a few grains of sal ammoniac seems the least injurious remedy. Convalescence is best left to nature. The results of this treatment are so favourable, that out of 6140 patients whom Professor Baug treated from 1826 to 1835, (among whom were nearly 1440 cases of typhus) only 340 died, including those who were moribund when brought into the hospital.—*Zeitschrift für die gesammte Medicin.*

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

—
Introductory Lecture, Oct. 3, 1842.

GENTLEMEN,—There are many diseases peculiar to women; they are all exposed to great suffering and danger during pregnancy and child-bearing, and many die from the acute disorders which follow delivery. Not only are the functions of the uterine system before conception often disturbed, but all the different parts of this system undergo morbid alterations of structure, which are frequently of a malignant nature, and excite, in their progress to a fatal termination, the most acute and protracted pain.

During the whole period of pregnancy, women are exposed to numerous accidents and diseases which endanger life; but it is in labour that they incur the greatest hazard, and endure the most intense suffering. The contents of the gravid uterus are expelled by a process which displays, in every stage, the most skilful contrivance, and in a great proportion of cases it is completed with safety both to the mother and child by the unassisted powers of nature. As soon as labour has commenced, the orifice of the uterus begins to open, that the child may pass through it, and the upper part contracts at intervals, with an amazing degree of regularity and force, till the whole ovum has escaped, and the great arteries and veins exposed by the separation of the placenta are effectually closed.

But this, like all the other functions of the animal body, is liable from various causes to great and sudden disturbance, or complete

interruption. The uterus may not possess the requisite power to expel the child; or, having done so, and the placenta also, its nervous energy may be insufficient to secure the permanent contraction of its walls, and blood may flow into the cavity till it is distended, and death take place before any apprehension of danger has been roused. Or the head of the child may be so large, or the pelvis of the mother so small or distorted, that it is impossible for delivery to take place, and the uterus and vagina be destroyed by the long-continued pressure they sustain; or lacerated, and the child forced through the rent into the peritoneal cavity. In other cases labour is rendered difficult and dangerous by the unfavourable position of the child within the uterus. Instead of the head presenting, or coming foremost, an arm descends, and the body of the child is placed across the pelvis, so that the longer and more forcibly the uterus contracts upon it, the more firmly are the shoulder and thorax impacted in the pelvis, and the more difficult does the operation of turning become.

The placenta, which usually adheres to the upper part of the uterus, is sometimes attached to the cervix or lower part, and then a dangerous flooding ensues, which nature has no power to arrest. The means she usually employs for the suppression of uterine hæmorrhage, if exerted in this case, would only aggravate the evil; and if artificial delivery were not performed, death would inevitably follow. The same is the consequence when the placenta has been detached from the upper part of the uterus, and where hæmorrhage follows the birth of the child; and not less destructive are the effects produced by the retention of the whole, or portions, of the after-birth within the uterus.

There are many other varieties of difficult and complicated labour, in which the unaided powers of nature are insufficient for the completion of delivery, and where the most

prompt and energetic and well-directed treatment is required to avert the danger. Even after the most easy and natural labours, when none of these accidents have occurred, and when all danger is apparently at an end, how often does inflammation of the uterus unexpectedly supervene, and run its course with a rapidity and violence equal to that of plague and cholera.

That such occurrences are not uncommon, the Reports of public institutions in different countries afford too abundant proof. 219,333 women were delivered in the kingdom of Wurtemberg, from the year 1821 to 1825, of whom there died 1248, or one in 175. At Hamburg, 5·57 women die in 1000 who have been pregnant or delivered. Of 448,356 females who died in the Prussian States in the course of fifteen years, between the ages of 14 and 45,—70·215, or nearly one-sixth, died either immediately in the act of delivery, or in childbed; and of 108 of the infants born, 1 in 108 cost the mother her life. In the mortality table for the city of New York for a period of thirty-two years, viz. from 1805 to 1836, both inclusive, it is stated that the births during this period ranged from 2 to 300,000; and that the whole number of deaths from childbed were only 1038. In the Dublin Lying-in Hospital, from 8th day of December, 1757, to the 31st day of December, 1832, there were 132,979 women delivered, of whom 1488 died. Of 16,654 women delivered in the same institution during a period of seven years, commencing November 1826, there were 1956 difficult cases, and of these 164 proved fatal. There were 409 preternatural presentations, 24 cases of uterine hæmorrhage before the birth of the child, and 64 between the expulsion of the child and placenta; 66 of retention of the placenta; 30 of puerperal convulsions; 240 of twins, and 4 of triplets; 97 of prolapsus of the funis; and 88 of puerperal fever, 56 of which were fatal. In the British Lying-in Hospital, Brownlow Street, 33,627 women were delivered between the year 1749 and 1824, of whom 433 died. In the first ten years 1 in 42; in the second ten years 1 in 50; in the third ten years 1 in 53; in the fourth ten years 1 in 60; in the fifth ten years 1 in 288; in the sixth ten years 1 in 231; in the seventh ten years 1 woman in 274. During the last fifteen years, in public institutions and in private practice, I have seen 55 cases of difficult and protracted labour, in which recourse was had to the forceps: above 100 in which delivery was effected by the operation of craniotomy, distortion of the pelvis being the most common cause of the difficulty: 35 in which premature labour was induced: 62 cases of arm presentation: 36 in which the placenta was adherent to the neck of the uterus, and 38 in which it was detached from the fundus,

and produced dangerous hæmorrhage: 7 fatal cases of retention of the placenta, and 19 in which great difficulty and danger were produced by portions of the placenta, or the entire mass, being left within the uterus beyond the usual period: 46 labours complicated with puerperal convulsions, and upwards of 250 of puerperal fever, or inflammation of the uterine organs in the puerperal state. Written histories having been preserved of these cases, they have now been collected and arranged for publication, in the hope that they may be found to illustrate, confirm, or correct, the rules laid down by systematic writers for the treatment of difficult labours, and supply that course of clinical instruction in midwifery, the want of which has been so often experienced by practitioners at the commencement of their career.

When women are attacked with puerperal convulsions, or flooding, or when any of the accidents occur during labour which have now been mentioned, they are wholly unable to make any effort to save themselves, and are placed in the same unconscious and helpless condition as those who have apoplexy, or concussion of the brain, or who are suffering from a violent external injury, or extensive wound, with great loss of blood. In no country in the world are women left to die in such circumstances without help; and in the most remote and barbarous ages, means, however rude and imperfect, have always been employed during the sufferings and dangers of child-bearing.

At first, females were solely employed for this purpose. The descendants of Abraham, while a wandering tribe, had midwives, and the Israelites continued to employ them while they remained in Egypt; and it is probable all the surrounding nations did the same, as they now do everywhere in the East. At what period, and in what country, physicians and surgeons were first consulted in cases of difficult labour, and in the diseases peculiar to females, is not known, but it is certain they were so in Greece at the time of Hippocrates, and that great attention was then given to all the different branches of midwifery. His works contain an account of many facts respecting the functions and diseases of the unimpregnated and gravid uterus, and difficult labours, which are evidently derived from extensive observation. He has described accurately the phenomena of menstruation, and traced the connexion which exists between the morbid states of this function, and hysteria, sterility, leucorrhœa, fibrous tumors of the uterus, and cancer. When the uterus is hard, and is low down near the pudenda, and the groins are indurated, and there is a sense of ardor, and sanguineous and fetid discharge, he says cancer may be suspected. The following passage proves that he was

well acquainted with the condition of the os uteri when affected with schirrhus, and that he was accustomed to examine the uterus by the vagina, in the same manner that we now do, to discover its organic diseases. "Si uteri in callum indurescant tum menses occultantur, tum corum os connivet, neque concepit et aliud quid esse videtur. Quod si attigeris, tanquam saxum illic esse videtur, os asperum est et multas habet radices, non leve aspectu, neque digitum admittit."—P. 658.

Some of the most important facts respecting the structure and functions of the human ovum had been ascertained at this early period, and particularly that the respiration and nutrition of the fœtus are effected by the placenta and umbilical cord. Hippocrates had an opportunity of examining a perfect ovum expelled about a month after conception, instead of six days, as he supposed, and it was probably the first entire ovum that he had ever seen, and I believe it was the first that ever was described. The feelings of admiration excited in his mind on first beholding it have, doubtless, since been experienced in an equal degree by the great anatomists "who have toiled in the mysterious researches of generation." "*Quam illa videns non sine admiratione spectavit, ego vere qualis referam. Ut si quis ovo crudo-externam testam undique auferat in quo interiore membrana contentus humor pelluceat, ad hunc fere modum (ut uno verbo dicam) se habebat liquor ille, prætereaque ruber erat et rotundus. Conspectiebantur autem fibrae albiæ et tenues in membrana cum sanie crassa et rubra contentæ, et ipsa membrana exteriore parte cruore ad instar sugillatorum suffusa erat. In cujus medio tenuæ quiddam extabat, quod mihi umbilicus esse videbatur et per illum primum respirasse, ex eoque protendebatur membrana tota genituram complectens.*"—P. 236.

In this concise description it is easy to recognize the decidua with its great plexus of veins gorged with maternal blood, the villi and cells of the chorion, the amnion, embryo, umbilical cord, and placenta, of which he has given a more minute account in the latter months of pregnancy, and of the functions it performs, and the membranes which surround it. The only parts of the human ovum to which there is no allusion here made, are the vesicula umbilicalis, which was first described by Albinus and Wrisberg about the middle of the last century, and the decidual cavity, discovered by Dr. William Hunter a few years after.

The works of Hippocrates likewise contain some important information respecting the diseases of pregnant women, particularly abortion, and the causes and symptoms of the death of the fœtus in utero. Blows, falls, violent terror, rupturing the membranes, diseases of the parents, are considered

by him to be the principal causes of the premature expulsion of the ovum. When the child is dead, he says, there is a sense of coldness in the abdomen, and it subsides, and the child falls like a stone within the uterus from side to side when the mother turns, and there is flaccidity of the breasts. If the menses appear during pregnancy, abortion follows, and the fœtus is expelled in a diseased condition. If much blood be discharged during labour without pain, there is danger that the child will be dead, or possess little vitality. Pregnant women affected with headache, sopor and weight of the head, he adds, are liable to be attacked with convulsions.

In difficult labours, where the head presented and could not be expelled by the natural efforts, it is probable that in the greater number of cases, after employing various remedies without effect, that he opened the head and extracted it with a hook or crotchet, as we do at the present time. If the fœtus lay across, presenting to the os uteri, whether it be alive or dead, he orders it to be pushed back and turned, so as that it may present with the head in the natural position; and to accomplish this purpose, the woman must be laid in bed with the nates raised higher than the head. If the child be alive, and presents with the arm or foot, he directs us to return them as soon as possible and bring down the head, or if it lies across, presenting with the side or hip, the same method, he says, must be used.

The operation here described is perfectly impracticable, and I cannot believe that he ever actually succeeded by it in accomplishing delivery where the arm presented, and the fœtus was mature, and the uterus contracting around it. Most of the women with preternatural presentations of the child would have died undelivered had some other method not been adopted, and that method consisted in mutilating the body with the crotchet, and bringing it away piecemeal, as we are sometimes still compelled to do where the operation of turning is inadvisable or impracticable. Hippocrates has compared the fœtus lying across the brim of the pelvis to an olive in a narrow-mouthed jar, which cannot be so easily extracted by the middle as when it presents with one end. But this comparison is both imperfect and incorrect, for the olive has neither head, nor superior nor inferior extremities, like the fœtus, and it is extraordinary that he failed, not merely to perceive these points of dissimilarity, but to discover that the feet of the child could readily be seized with the hand and extracted, while it was impossible for the hand to grasp the head on account of its bulk. The slightest reflection on what he must have often seen take place in presentations of the feet and nates, one might suppose would

have led to this discovery, which comprehends the whole principle of the operation of turning; a discovery which will ever be regarded as one of the most important in midwifery, and which has gained for its author the most lasting honour. That a circumstance of such vast importance, and now apparently so obvious, should not only have escaped the observation of Hippocrates, but of all who followed him for 2000 years, is truly a matter of the deepest astonishment, and seems to illustrate in a striking manner what Dr. William Hunter has said respecting the discovery of the circulation of the blood. "It is the more amazing that this discovery was left for Harvey, when we consider that he was near an hundred years after Vesalius, in which interval many great men had appeared, and anatomical schools had flourished in many different parts of Europe. And what is still more astonishing, Servetus first, and Columbus afterwards, both in the time of Vesalius, had clearly given the circulation of the blood through the lungs, which we may reckon at least three quarters of the discovery: and Cæsalpinus had, many years before Harvey, published in three different works all that was wanting in Servetus to make the circulation quite complete. But Providence meant to reserve this honour for Harvey, and would not let men see what was before them, nor understand what they read."

Midwifery remained nearly in the same condition in which it was left by Hippocrates till the middle of the 16th century, when lying-in wards were opened at Paris in the *Hôtel Dieu*, and opportunities were afforded of witnessing all the phenomena of natural and difficult labour, and the diseases of puerperal women. The great discovery to which I have now alluded was then made by Ambrose Paré, and described in the following passage in the 15th chapter of his translated works, 1665. "It is supposed to be a natural and easy birth when the infant cometh forth with his head forwards, presently following the flush of waters, and it is more difficult when the infant cometh forth with the feet forwards; all the other waies are most difficult; therefore midwives are to be admonished that as often as they perceive the child to be coming forth none of these waies, but either with his belly, his back forwards as it were doubled, or else with his hands and feet together, or with his head forwards and one of his hands stretched out, that they should turn it and draw it out by the feet; for the doing whereof, if they be not sufficient, let them crave the assistance and help of some expert chirurgian." The method the surgeon ought to adopt is described more particularly in Chap. XXVI. which is headed, "Of the Chirurgical Extractions of the Child from the Womb either Dead or Alive;" and it is obvious from the

following passage, that he had met with cases of arm presentation in which the feet could not be brought down and the turning accomplished till the arm was removed, and not then. "But if the infant lieth as if he would come with his hands forwards, or if his hands be forth already, so that it may seem he may be drawn forth easily that way, yet it must not be so done, for so his head would double backwards over his shoulders, to the great danger of his mother. Once I was called unto the birth of an infant whom the midwives assayed to draw out by the arm, so that the arm had been so long forth that it was gangrenate, whereby the child died. I told them presently that his arm must be put in again, and he must be turned otherwise. But when it could not be put back by reason of the great swelling thereof, and also of the mother's genitals, I determined to cut it off with an incision-knife, cutting the muscles as near as I could to the shoulder, yet drawing the flesh upwards, that when I had torn off the bone with a pair of cutting pincers it might come down again to cover the shivered end of the bone, lest otherwise, when it was thrust in again into the womb, it might hurt the mother: which being done, I turned him with his feet forwards, and drew him out as is before said. But if the tumor, either naturally, or by some accident, that is to say by putrefaction, which may perchance come, be so great that he cannot be turned according to the surgeon's intentions, nor be drawn out according as he lieth, the tumor must be diminished, and then he must be drawn out as aforesaid, and that must be done at once." Except some judicious observations on the treatment of retention of the placenta, there is nothing besides relating to midwifery of the slightest importance in the works of Ambrose Paré. Although he had enjoyed frequent opportunities of examining the gravid uterus in those who had died during pregnancy, and had repeatedly performed the Cæsarean operation on the living body, he never became acquainted with the ordinary position of the fœtus in utero, but considered it altogether uncertain and variable, both in living and dead women. This fact, indeed, was not known to many for a hundred years after this period, and the fœtus is consequently represented by figures in their works, in the most grotesque and unnatural attitudes, as if flying, jumping, walking erect, kneeling and swimming; in every position, indeed, except that in which it is placed by nature.

In 1609, about thirty-six years after Paré, his pupil, Guillemeau, published a work entitled, *De l'Heureux Accouchement des femmes ou il est traite du gouvernement de leur grossesse, De Leur Travail naturel et contre nature, Du traitement estant accouchees, et de leurs maladies.* He has

described the symptoms and treatment of natural labour with the greatest fidelity, and the management of new-born children and women in the puerperal state. He recommends a broad bandage to be applied around the body at the commencement of labour, and to be gradually tightened as it proceeds, and also a permanent binder, as is done at the present time, when the whole process is finished. Where the placenta did not immediately follow the child, he made pressure with the hand over the fundus uteri to excite the contractions, and employed all the means now in common use to promote its expulsion. The immediate extraction of the placenta after the birth of the child became, however, in no long time, almost the general practice, and continued to be so till about the middle, or near the end, of the eighteenth century, when Dr. W. Hunter made the unfortunate experiment of leaving it wholly to nature.

Respecting the diseases of pregnant and puerperal women, there is nothing of any great value in the work of Guillemeau: its importance is derived from the history it contains of difficult labours, which is far more accurate and complete than any that had ever before appeared, and in which he has embodied the results of all the observations he had made during a period exceeding forty years. "When a surgeon is called to a case of difficult labour, he should first inquire into the cause of the difficulty, and all the causes, he observes, may be referred to four heads—1, to the mother; 2, to the infant; 3, to those things that are connected with the infant; and 4, to external circumstances. Proceeding upon this principle of classification, similar in many respects to that adopted by Dr. Merriman in his excellent practical work on Difficult Parturition, he arranges all the varieties of laborious and difficult delivery, and describes their treatment under the following sixteen orders:—

1. Of the means of assisting women who have difficult labours.
2. Of the different labours which are accomplished by manual operation.
3. Of labours with hemorrhage and convulsions, and their treatment.
4. The means of affording relief when the afterbirth presents the first.
5. The delivery of dead children, and when they are swollen or distended within the uterus.
6. Cases of malposition of the head.
7. Presentation of the superior extremities.
8. Of the head and the two arms together.
9. Of the feet.
10. Of the feet and hands together.
11. Treatment of cases in which the infant comes double, or the back, loins, sides, shoulders, or nates present.
12. Presentations of the thorax and abdomen.
13. Cases of twins, one with the head presenting, the other the feet.
14. Twins, the feet of both presenting.
15. Retention of the placenta.
16. On the Cæsarean section, which he condemns after

seeing it unsuccessfully performed five times.

We have here not only all the great operations of midwifery then known minutely and accurately described, but we have the important pathological fact first clearly stated, that the placenta may present or come before the child; that this gives rise to a dangerous hæmorrhage, which nature is unable to suppress; and that the most safe and expedient means of arresting it is to deliver immediately by passing the hand into the uterus and bringing down the feet. He has made no observation from which it can be justly inferred that he believed the placenta to have been originally adherent to the upper part of the uterus, and to have descended from thence to the cervix. This is an erroneous hypothetical opinion which was first adopted by Daventer at a much later period, and which has been also attributed unjustly to Hippocrates, although he had formed no theory on the subject, having merely asserted that the placenta should come after the child, for the child cannot live if it comes first, because the child derives its life from the afterbirth, as a plant does from the earth. Portal was the first, in 1685, who stated that the placenta was found, not merely at the cervix uteri, but adhering to it all round. In the account of his sixty-ninth case he says, "*Je sentis l'arriere faix, qui se presentoit, et qui estoit fort adherant, et attaché à l'orifice de la matrice de toutes parts.*" In the histories of all the other cases the same circumstance is expressly stated, and the same treatment is recommended as that employed by Guillemeau, and which has continued to be the practice in common use to the present time.

In cases of hæmorrhage where the placenta did not present, but had been detached from the fundus uteri, Guillemeau likewise had recourse to artificial delivery; and for the knowledge of this practice he most candidly and honourably states that he was indebted to Ambrose Paré. His love of truth and of justice was such, that he would not claim an honour which belonged to another, though Paré had been dead for many years, and had made no mention of the discovery in his works.

Mauriceau and Smellie are the only individuals, who have devoted their lives to the study and practice of midwifery during the last two hundred and thirty years, whose contributions to the science, in point of originality and importance, can be compared with those of Guillemeau. Mauriceau practised midwifery forty years in Paris, and he considered no department of medicine or surgery superior to it in dignity and utility. For twenty-five years he preserved faithful histories of all the important cases which came under his care, and out of three thousand he selected seven hundred of the

most important for publication. "Among these cases," he observes, "will be found examples both to imitate and avoid; and since I have had the public good alone in view in relating them, I have recorded the unfortunate as well as the fortunate results of my practice, and have omitted nothing which long experience has taught me might in any way contribute to the health and relief of women in pregnancy and in child-bed, and to the cure of the diseases to which they are at all times exposed."

Mauriceau has recorded the histories of thirty-seven cases of uterine hæmorrhage, in which the placenta did not present, but had originally adhered to the upper part of the uterus, and been afterwards detached. Twenty-one of these cases occurred before 1682; and in most of them he delivered artificially by turning the child, as he had done in the sixteen cases of placental presentation which he has likewise recorded, and as Paré and Guillemeau were accustomed to do in all cases of flooding in the latter months of pregnancy. On the 9th June, 1682, he says, "I delivered a young woman in the eighth month of pregnancy, who had uterine hæmorrhage caused by a violent fall upon the knees four days before. During her whole labour she had only slight pains in the abdomen, which produced no effect. As the hæmorrhage was moderate, and the uterus was gradually dilating, I committed the labour to nature, contenting myself with rupturing the membranes of the child. There is no account given of the circumstances which led him to make this important change in the treatment of cases in which the placenta did not present, and to adopt that improved method of treatment which was, at a later period, so strongly recommended by Puzos, and considered by him as his own discovery. No fact of the slightest importance has since been discovered respecting the causes and treatment of uterine hæmorrhage in the latter months of pregnancy, and to Mauriceau the honour is due of having first pointed out the efficacy of rupturing the membranes where the placenta does not present.

The midwifery forceps, which enables us to save the lives of some children, which we would otherwise be compelled to sacrifice, was invented by Chamberlayne early in the seventeenth century, some years, probably, before the publication of Mauriceau's great systematic work in 1668. But no description was given of the instrument before 1733, and no precise rules laid down for its use. Chapman then stated that it could never be employed with advantage till the os uteri was dilated, and the head had descended into the pelvis. Smellie, soon after, having ascertained with greater precision the manner in which the foetal head passes through the pelvis, was enabled to lay down

still more precise rules for its application. Although Smellie's works contain many cautions against the abuse of the forceps, there nevertheless sprung up, soon after their publication, both in this country and on the continent of Europe, a singular want of confidence in the powers of nature, and a mischievous predilection for the employment of instruments in the practice of midwifery. The process of labour, instead of being regarded as a vital process, depending on nervous energy and muscular contraction, came to be considered as a function purely mechanical. "The whole art of midwifery," observes a learned professor, "is founded on geometrical principles; it is certain in all its operations, like the laws of motion, and might be reduced to the following simple problem in mechanics:—an extensible cavity of a certain capacity being given, to draw through it a flexible body of a given length and breadth, by an opening dilatable to a certain extent." "Parturition is a problem in mechanics," another exclaims: "a body is to be put in motion, a moving power is given, and there is a resistance to be overcome. Whenever the relation in which each of these three points of the problem stand to one another is in such a ratio that no movement or motion can be produced, the labour is at a stand." This application of mechanical principles to the practice of midwifery has been greatly promoted by the writings of Solayrès, Baudeloque, Gardien, Capuron, and many other continental, and some English and American, authors during the last forty years. The result of this has been, that in some public institutions there have been 300 forceps cases in 2,093 labours, or 1 in 7; and in others 1 in 14, 1 in 16, and 1 in 31 labours. From these facts it seems not very improbable that the time might actually arrive when no woman would be allowed to be delivered by the natural efforts; which another learned professor is said to have expressed a hope he would live to see. Dr. William Hunter had great confidence in the powers of nature, and inculcated in his lectures, with the happiest effect, the propriety of trusting much, in all cases, to their unassisted efforts, and of employing instruments only where absolutely necessary. He thus powerfully contributed to correct the evil I have now described, and which had prevailed also to a great extent in England. The writings of Drs. Osborn and Denman likewise assisted, and those of the latter contain by far the best account we yet possess, not only of the forceps, but of the operation of turning, craniotomy, and the induction of premature labour, which was first proposed by Dr. Macaulay in 1756.

During the present century many subjects relating to the structure, and functions, and diseases of the uterine system, at the different periods of life, which had remained for ages

involved in the greatest obscurity, have been successfully explored. Of these perhaps the most interesting are the researches which have been made into the structure of the human ovum before impregnation, and into the condition of the ovaria during menstruation and after conception; the circulation of blood in the human ovum during the early months; the pathology of the ovum at the different periods of pregnancy; and the causes of the death of the fœtus and its premature expulsion from the uterus. To these may be added the investigations which have been made into the structure of the various tumors of the uterus which are not of a malignant nature, and those which are cancerous. The nature of several puerperal diseases has likewise been determined by morbid anatomy during this period, and the diagnosis of pregnancy has been greatly improved by the employment of auscultation.

Perhaps I may be permitted on this occasion to allude to some labours on the nervous system of the uterus, which were commenced four years since, and which have now been brought to a successful termination. Dr. W. Hunter was the first who distinctly traced the great sympathetic and sacral nerves into the uterus, and suspected that the nerves enlarge during pregnancy. As he never examined the nerves of the unimpregnated uterus, and saw the nerves of the gravid uterus dissected only in one subject, he could not positively assert that they increased after conception. "I cannot," he observes, "take upon me to say what change happens to the system of uterine nerves from utero-gestation, but I suspect them to be enlarged in proportion as the vessels."

Mr. John Hunter denied that the nerves of the uterus ever enlarged during pregnancy in the smallest degree. "The uterus in the time of pregnancy," he says, "increases in substance and size probably fifty times beyond what it naturally is, and yet we find that the nerves of this part are not in the smallest degree increased. This shows that the brain and nerves have nothing to do with the actions of a part, while the vessels which are evident increase in proportion to the increased size: if the same had taken place with the nerves, we should have reasoned from analogy." Dr. W. Hunter left no dissected preparation of the nerves of the uterus, nor did Mr. John Hunter, to support their conflicting statements; and in 1838 there were no preparations of the nerves of the human unimpregnated or gravid uterus, nor of the uterus of any of the lower animals, in this country. In 1822, Tiedeman published a description of the nerves of the uterus, with two plates, in which only a few small branches of nerves from the great sympathetic were represented, accompanying the uterine arteries upon the sides of the lower part of the uterus. The fundus uteri,

which is possessed of the greatest degree of contractile power, is, you see, quite destitute of nerves. In 1823, Lobstein stated that the uterus both before and after conception is very sparingly supplied with nerves; and in 1829, Professor Osiander declared that the nerves of the human uterus had never been seen, either by himself or by any other anatomist, and that he could only assert, as Galen had done, from the irritability of the uterus, that it did possess nerves.

In the last volume of the Philosophical Transactions, there is a paper on the Nervous Ganglia of the Uterus, in which it is stated, from dissections of the unimpregnated uterus, and of the gravid uterus in the third, fourth, sixth, seventh, and ninth months of pregnancy, that there are many large ganglia formed on the uterine nerves, and on those of the vagina and bladder, which enlarge with the coats, blood-vessels, and absorbents of the uterus during pregnancy, and which return after parturition to their original condition before conception takes place. In the two engravings which accompanied the paper, are represented these ganglia and nerves of the uterus, vagina, and bladder, in the fourth month of pregnancy. But these constitute but a small portion of the nervous system of the human uterus; and the forthcoming volume of the Philosophical Transactions will contain a further account of the nervous structures of that organ, with the engraving I now shew you. In this plate have been accurately represented all the great blood-vessels and nerves of the gravid uterus, on the left side, at the end of the ninth month of pregnancy. About an inch above the origin of the mesenteric artery each cord of the great sympathetic nerve sends numerous branches which form a plexus around the trunk of the artery, which accompany the ramifications of the vessel, and particularly the hemorrhoidal artery, to the rectum. The two cords of the great sympathetic, after giving off these nerves, pass down before the aorta, about two inches below its bifurcation, where they separate, the left passing down behind the hypogastric blood-vessels to the side of the neck of the uterus, and terminating in what has been called the left utero-cervical or hypogastric ganglion. This you see is a very great ganglion, and covers a large part of the cervix uteri, and gives origin to the nerves of the vagina and bladder, and many of the rectum. All the blood-vessels of this ganglion have been injected, and an artery passes up from it, with a plexus of nerves, along the whole body of the uterus to the principal trunk of the spermatic vein, close to the ovary, and there terminates in another ganglion, nearly equal in size to the utero-cervical ganglion. From this spermatic ganglion the fundus uteri is supplied with nerves, and the sper-

matic nerves are sent off, and which pass up with the spermatic artery and vein to the renal plexus. Besides these ganglia, there are others of great size situated immediately beneath the peritoneum, between which and the spermatic and hypogastric ganglia numerous large plexuses of nerves, accompanied with arteries, pass. But what you see represented in this engraving is only the fourth part of the ganglia and nerves of the gravid uterus at the full period; and if it were asserted that these nervous structures bear to the uterus nearly the same proportion that the optic nerve and retina do to the eye, it is probable there would be little exaggeration of the truth. It is chiefly by the influence of these nerves that the uterus performs the varied functions of menstruation, conception, and parturition; and it is solely by their means that the whole fabric of the nervous system sympathizes with the different morbid affections of the uterus. If these nerves of the uterus could not be demonstrated to exist; if, as Mr. Hunter asserted, the nerves of the uterus were not enlarged in the smallest degree during pregnancy, and that the brain and nervous system had nothing to do with the actions of the uterus, its physiology and pathology would be completely inexplicable.

In all civilized countries midwifery is taught in the medical schools, and the propriety of employing physicians and surgeons in its practice is generally acknowledged. No apology, therefore, can now be required, in behalf of a branch of medical science so eminently conducive to the best interests of society, and a knowledge of which is essentially necessary not only to accoucheurs, but to all who are engaged in the practice of medicine and surgery.

In this course of lectures I shall endeavour to communicate to you a full account of all that is at present known respecting the structure, functions, and diseases of the uterine system, at the different periods of life, and prepare you for the discharge of those duties which will hereafter devolve upon you as practitioners of midwifery. It is a grievous error to suppose that a knowledge of midwifery is to be acquired more easily than a knowledge of any of the other branches of medicine. If you would excel in it, equal, perhaps greater, exertion will be necessary. Excellence, as Sir J. Reynolds has observed in his address to the students of the fine arts at the Royal Academy, is never granted to man but as the reward of labour. It argues, indeed, no small strength of mind to persevere in habits of industry without the pleasure of perceiving those advances; which, like the hands of a clock, whilst they make hourly approaches to their point, yet proceed so slowly as to escape observation. I need not, therefore, enforce the necessity of continual

application. You must have no dependence on your own genius. If you have great talents industry will improve them. If you have but moderate abilities, industry will supply their deficiency. Nothing is denied to well directed labour; nothing is to be obtained without it."

ON THE
USE OF DIFFERENT FORMS OF THE
SAME MEDICINE IN EQUIVA-
LENT DOSES.

To the Editor of the Medical Gazette.

SIR,

In a paper "On the dubious efficacy of Digitalis," which you did me the favour to publish in the *MEDICAL GAZETTE* for June 4, 1841, I quoted the opinion of Dr. Blackall upon the extreme difficulty of making "a just calculation of the relative strength of the infusion, the tincture, and the powder of digitalis."

This difficulty, noticed by Dr. Blackall in reference to digitalis, is experienced in calculating the relative strength of the various preparations of other drugs, but I believe it may be materially lessened by the use of medicines carefully prepared and exhibited under similar conditions in equivalent doses; or in such as contain equal quantities of active principle.

Inattention to the degree of concentration in which the active principles of drugs exist under various pharmaceutical forms, I believe often leads to error in proportioning their respective doses, as well as to an inaccurate estimation of their efficacy, and the chief object of this communication is to point out a few incongruities between the doses of several pharmaceutical preparations made according to the directions of the *London Pharmacopœia*.

It is not any part of my design to insist upon the necessity of giving large or small doses, nor to assert that different pharmaceutical preparations of the same drug can be made to correspond in chemical composition; for this correspondence must necessarily be prevented by the nature of the reagents applied to the drugs; but I believe the solvents used in making some of the officinal preparations named in the *London Pharmacopœia* are capable of dissolving all the active principle of the drugs to which they are applied, and

that the residue, which is insoluble in them, is inert. Upon this belief, I consider the strength of some liquid preparations may be compared with that of the solid drugs with which they were respectively made, and that their active principles may be administered in equivalent doses under the solid or liquid forms. But this rational mode of prescribing different preparations of the same drug is not invariably pursued; and the absolute quantity of active principle prescribed under similar conditions of disease, will be found to differ materially, without any evident reason for the difference existing referrible to the patient.

The incongruities to which I allude may be observed between the ordinary doses named in most posological tables and books on *materia medica*, and a few examples will suffice to render the above remarks intelligible.

Thus, one eminent authority states the ordinary dose of *cantharis*, in powder, to vary between gr. ss. and gr. ij.; and the dose of the tincture of *cantharis* between ℥x. and ℥xx. Now assuming that the *spiritus tenuior*, which is used in making the tincture of *cantharis*, is capable of extracting all the active principles of the fly, and that the maximum and minimum doses of the two preparations named above are respectively equivalent to one another, the larger to the larger, the smaller to the smaller—or that gr. ss. of the pulverised *cantharis* contains the same quantity of active principle as ℥x. of the tincture, and that grs. ij. contain as much as ℥xx.—then the practitioner, who, for the sake of argument, I will suppose, has produced certain effects on his patient with the powder administered in doses of gr. ss. will reasonably expect to produce similar effects with the tincture given in doses of ℥x. under similar conditions; but in this expectation he will be disappointed, and if he calculates the degree of concentration of the active principle in the official tincture from the quantity of materials directed to be employed in the *London Pharmacopœia*, he will perceive these doses do not contain equal quantities of active principle; for, fʒi. of the tincture, or ℥lxx., contain the soluble parts of $\frac{1}{4}$ of a grain of *cantharis*; and, consequently, ℥x. or $\frac{1}{4}$ of ℥lxx. contain $\frac{1}{4}$ of $\frac{1}{4}$, or $\frac{1}{16}$ of a grain of *cantharis*: hence, a dose of ℥x. of the

tincture is the equivalent of $\frac{1}{16}$ of a grain only, and not of gr. ss. of the powder.

The ordinary dose of gr. ss. of *cantharis*, on the same calculation, would be the equivalent of ℥xl. and gr. ij. of fʒij. $\frac{3}{4}$, or nearly ʒiij. of the tincture of *cantharis*, which is a dose considerably larger than that directed to be given in posological tables and works on *materia medica*.

I have prescribed the tincture to between 20 and 30 patients in St. Thomas's Hospital, some of whom took it in doses of ℥xxv., others in doses of ʒss. raised to ʒiij.

To three patients the pulverized fly was given in doses increased from gr. j. to grs. ijss.; and, to one person, from gr. j. to gr. ix., repeated thrice in 24 hours.

But I am unable to speak confidently of the relative strength of these preparations; and as it is not an object of this paper to advocate or deny the absolute efficacy of the medicines named in it, I may conclude these remarks on *cantharis*, by assuring the reader that the patients were questioned four or five times weekly relative to the effects of the medicine they were taking, and that in no case was any greater inconvenience experienced than a slight degree of ardor urinæ, and in a large majority of the cases no inconvenience whatever resulted from its use.

A very remarkable incongruity may be observed between the ordinary doses of the powder and tincture of *cubebæ*. The ordinary dose of the powder is stated in posological tables and works on *materia medica* to be ʒj.; that of the tincture fʒj.

But the equivalent of ʒj. of the powder is fʒj., or eight times as much as the ordinary dose of the tincture; and the equivalent of the ordinary dose of the tincture, or fʒj., is one-eighth of 60, or gr. viiss. of *cubebæ*, a quantity much less than that which is usually prescribed in one dose.

The ordinary dose of the dried squill-bulb given for the purpose of promoting expectoration is gr. j., and that of the *T. Acetum Scillæ* is fʒss.

But fʒss. of the liquid preparation contains the soluble parts of very nearly gr. iiiss. of the dried solid; and much more than is usually administered as an expectorant.

The acrid nature of squill is well known, and the practitioner who di-

rects the use of the *Acetum Scillæ* in doses of $\text{f}\text{ss.}$, repeated thrice or four times in 24 hours, with the view of affecting the pulmonary organs, will in all probability irritate the alimentary canal, and unnecessarily excite vomiting and purging.

The equivalent of the ordinary dose of gr. j. of the powder, under the form of the *Acetum Scillæ*, is only $\text{m}\text{viii}\text{ss.}$, and is much less than that usually prescribed for an adult.

It may, perhaps, be instructive to notice the ordinary doses of the officinal preparations of the *Hyoseyami Folia*, of which the extract and tincture are very frequently administered, and occasionally, also, the dried leaves themselves: the ordinary dose of the latter preparation is gr. v.; of the extract gr. v.; and of the tincture $\text{m}\text{xv.}$, or $\text{m}\text{xx.}$

Now on referring to the formula in the *Pharmacopœia Londinensis* for making the officinal tincture of *hyoseyamus*, $\text{f}\text{sj.}$ of it may be calculated to contain the soluble parts of gr. viiss. of the dried leaves; and gr. v. of the same leaves are the equivalents of $\text{m}\text{xl.}$, or twice the quantity of this tincture, which is usually administered as an ordinary dose. A concentration of the active principles of vegetable substances is effected by the process of making extracts; consequently, gr. v. of the extract of *hyoseyamus* should contain more active principle than gr. v. of the dried leaves.

The effects of gr. v. of the extract, so far as I have been able to observe them on hospital patients, are slight and equivocal; the effects of a smaller dose may be expected to be still less manifest; consequently, gr. iiss. of the dried leaves, in which inert compounds are associated with extractive and active principles, must be more than half as weak as gr. v. of the extract; but gr. iiss. of the dried leaves are the equivalents of $\text{m}\text{xx.}$ of the tincture, and are therefore probably less efficient than gr. iiss. of the extract.

Similar incongruities may be observed between the ordinary doses in which the preparations of the *Digitalis Folia* are often prescribed. There are authorities for prescribing the *pulvis digitalis* in doses of gr. ss.; the infusion of its leaves, in doses of $\text{f}\text{ss.}$; and their tincture, in doses of $\text{m}\text{x.}$ Now in

order to compare the relative strength of these preparations, the doses in which they are given should contain equal quantities of active principle: but if the degree of concentration in which the active principle of the leaves of *digitalis* exists in the tincture and infusion be calculated from their formulæ in the *Pharmacopœia Londinensis*, these doses will not be found arithmetical equivalents of one another.

Thus $\text{f}\text{sj.}$ of the officinal infusion of the *Pharmacopœia Londinensis* for 1836, contains the soluble parts of very nearly gr. iij. of the leaves; and $\text{f}\text{sj.}$ of the tincture contains the soluble parts of gr. vj. of the leaves; consequently, gr. ss. is the arithmetical equivalent of less than $\text{f}\text{ss.}$ of the infusion, or $\text{f}\text{sj}\frac{2}{3}$ exactly, instead of $\text{f}\text{siij.}$; and of $\text{m}\text{v.}$ of the tincture, instead of $\text{m}\text{x.}$

From this calculation the ordinary dose of the infusion is very nearly three times stronger than the ordinary dose of the powder; and probably, owing to this difference being overlooked, the infusion of *digitalis* enjoys the reputation of being the most active preparation of this plant; and the patient who swallows three times as much of its active principle in the liquid form as exists in its solid form, will be proportionably sooner affected by it.

Some recent observations of the effects produced by the powder and tincture of *digitalis*, made with leaves of the same quality, upon my patients in St. Thomas's Hospital, although limited in point of number, tend to show that these preparations, if given in equivalent quantities, will affect the system in nearly the same period.

The results of these observations, however, should only be considered as approximations to the truth, and as such are exhibited in the two following tabular forms; the first of which exhibits the results obtained with the tincture; the second with the powder of *digitalis*. The use of the medicine was, in every case, considered to be indicated by the symptoms; the doses were repeated in most cases every eight hours, and their effects noticed on three or four days in each week.

The cases were too few to require a distinction to be made between the sexes, and all the patients, excepting one female, were above 20 years of age.

FIRST TABLE.

Names.	Quantity of Tincture of Digitalis taken before any sensible effects were produced.	Time before effects were observed.	Doses.
1 Thornton	f. ʒviiss.	10 days	℥xv. t. d.
2 Gosley	ʒiij. $\frac{2}{3}$	5	℥xxx. t. d.
3 Croker	ʒiij. $\frac{1}{4}$	7	℥xv. t. d.
4 Hill	ʒvj. $\frac{1}{2}$	7	℥xv. t. d.
5 Townsend	ʒviij.	11	℥xv. to ℥xx. t. & 6tis.
6 Thurrorback	ʒv. $\frac{1}{2}$	9	℥xv. t. & 6tis.
7 Deane	ʒv. $\frac{1}{2}$	7	℥xv. t. d.
8 Griffiths	ʒix.	12	℥xv. t. d. & 6tis.
9 Runcorn	ʒiiss.	4	℥xv. t. d.
10 Hayward	ʒiiss.	4	℥xx. t. d. & 6tis.
11 Simms	ʒv. $\frac{2}{3}$	6	℥xx. t. d.
12 Cushion	ʒvj.	6	℥xv. t. d.
13 Donovan	ʒiv.	10	℥xv. t. d.
14 Cawnor	ʒvss.	7	℥xv. t. d.
15 Wallington	ʒiv.	5	℥xv. t. d.
16 Arden.	ʒij. $\frac{2}{3}$	7	℥xij. to ℥xv. t. d.

SECOND TABLE.

Names.	Quantity of the Pulvis Digitalis taken before any sensible effects were produced.	Time before effects were produced.	Doses.
1 Beaumont	gr. xijj.	6 days	gr. ss. to gr. iss. t. d.
2 Cockland	gr. xij.	6	gr. ss. to gr. j. t. d.
3 Crawley	gr. lv.	16	gr. ss. to gr. ij. t. d.
4 Harris	gr. lxxijj.	18	gr. ss. to gr. iiss. t. d.
5 Davis	gr. xxv.	12	gr. ss. to gr. iss. t. d.
6 Galloway	gr. xxijj.	10	gr. ss. to gr. j. t. d.
7 Emery	gr. xlij.	11	gr. ij. to gr. iij. t. d.

The total quantity of the tincture swallowed by sixteen patients, in 117 days, amounted to nearly fʒlxxij.; consequently the average quantity taken by each patient was fʒv. $\frac{1}{5}$; and the average time required to affect the system of each was $7\frac{1}{3}$ days.

From the numbers in the second table, it appears that the average quantity of pulverized digitalis swallowed by each of the seven patients was gr. xxxiv.; and the average time $11\frac{2}{7}$ days.

Now it is satisfactory to observe, with reference to the relative strength of these two preparations, that fʒv. $\frac{1}{5}$ of the tincture contain, very nearly, the soluble parts of gr. xxx. of the powder; a quantity which differs in a very trifling degree from the average quantity of the pulverized leaves. But whether this near approximation of the two numbers was the result of accident, and not of an equality of strength between the two preparations, remains

to be determined by more numerous observations. I am, however, inclined to believe it is not very far from the truth; and that these quantities of the two preparations might have been made to affect the system of the same patient in the same period of time, had the first doses in which the pulverized leaves were given been invariably equivalent to those of the tincture; but, for reasons which it is unnecessary to specify, they were always, excepting in one case, less than the first doses of the tincture, as appears in the third column of the two tables. Moreover, the dose of the tincture was repeated, in several cases, more frequently in the twenty-four hours than that of the powder.

A less proportional quantity, therefore, of the powdered leaves was swallowed by seven patients, than of the tincture by sixteen patients, in the same period; and to this difference

chiefly may be attributed, I think, the greater average time which was required to affect the system of the seven patients, as represented in the second table.

The idiosyncrasy of the patients, and the nature of their diseases, among other circumstances, may have tended to delay the manifestation of the effects of the medicine in some cases, and to expedite it in others; but these circumstances would have equally influenced the action of the tincture as well as that of the powder, and may be considered of no consequence in comparing the average results above noticed.

The preparations administered to the twenty-three patients were made with the mature leaves; but to five other patients a tincture of digitalis was administered which had been made of

the immature leaves, and its effects were carefully noticed.

It was administered in doses of $\text{f}\text{3ss}$. every eight hours, and, in two cases, augmented to $\text{f}\text{5j}$., continued, on an average, seven days, until each patient, on an average, had drank $\text{f}\text{3iiss}$. of the tincture, before any unequivocal signs of the system being under its influence could be observed. The average quantity deduced from these cases was much greater than that from the sixteen cases noticed in the first table; and the results tend to prove that the use of the tincture of digitalis, made with the immature leaves, in ordinary doses, will lead to inert practice.

The columns of the subjoined table exhibit, at one view, the discrepancies to which I have alluded above, as sources of the variable results obtained

Drugs.	Ordinary dose of powder.	Dose of Tincture.		Dose of Infusion.	
		Ordinary.	Equivalent.	Ordinary.	Equivalent.
Cantharis	gr. ss.	℥x.	℥xl.	fʒiv.	fʒj. ̄2
Cubeba	gr. lx.	fʒj.	fʒj.		
Digitalis	gr. ss.	℥x.	℥lv.		
Hyoscyamus	gr. v.	℥lxx.	℥xl.		
Acetum.					
Scilla	gr. j.	fʒss.	℥viiiiss.		

by the use of different preparations of the same drug in ordinary doses, and which, I believe, might be partly obviated by substituting equivalent doses.

Many other examples might be cited; but enough has been said to explain the object of this paper; and should you think my remarks possess

any general interest, you will oblige me by publishing them in your journal.

I am, sir,

Your obedient servant,

HENRY BURTON, M.D.

Physician of St. Thomas's Hospital.

41, Jermyn Street,
August 29th, 1842.

ON THE TREATMENT OF SYPHILIS BY TARTARIZED ANTIMONY.

By ALFRED SMEE, F.R.S.

Surgeon to the General Dispensary, Aldersgate Street; to the Bank of England, &c.

(For the Medical Gazette.)

Of all the diseases to which the human frame is liable, there is none wrapped in greater mystery, either in the cause of its production, the varieties it assumes, the rationale of its treatment, the duration of its effects, the injury it

inflicts, or the power which it possesses of being transmitted from generation to generation, than syphilis. It is by no means my present intention even to attempt to unravel these various mysteries, seeing how they have perplexed the brightest stars which have adorned our profession. Nevertheless, at the present time, I beg to be allowed to call the attention of all interested in the treatment of this horrible malady to a few prefatory remarks on a simple line of treatment, whereby its duration may frequently be rapidly cut short, and its injurious poison shaken from the system.

The employment of tartarized antimony for the cure of syphilis, in the peculiar way in which I now recommend it, occurred to my mind from noticing the effects of that potent remedy in removing various other diseases. The effect of tartarized antimony upon the system is rapid, and is very different when administered in different ways. If given in large doses it produces great effect upon the stomach, irritating that organ, exciting it to vomiting, and, from its action thereon, reacting upon the brain and nervous system. This mode of administration is very well where we desire to cause syncope for the purpose of reducing a dislocation, but this kind of action is precisely the one which we have to avoid when the remedy is given for the cure of syphilis. In this latter case, we give very small doses frequently repeated, so as to charge the system with the remedy, which then appears to irritate the capillary system and incite it to action: the whole excretory apparatus of the entire body being then irritated in the same way as the stomach in the former case, strives to throw off the new agent, and with it practically we have reason to believe that the syphilitic poison is ejected.

With regard to local applications best adapted for syphilitic patients, we should be careful always to employ such as can thoroughly decompose, and combine with, the puriform discharge; for if we consider that every part of the body, solids as well as fluids, is endowed with vitality, and all particles grow by like matters being attracted to like matters, it must be highly desirable to destroy the means by which such an increase might take place. If, however, we deny the hypothesis, it would be wise to act practically on the possibility, especially when universal experience shows that the surface of every sore cannot be too free from puriform secretions. In no case is this fact better seen than if we compare the rapid progress which syphilis usually makes in the lower orders, who, by paying no attention to cleanliness, let the pus accumulate, with the progress of the disease in those in better circumstances, who are exceedingly particular in this respect. Puriform discharges seem to be best removed by such substances which either have much affinity for, or are easily decomposed by, hydro-

gen. Nitric acid, nitrate of silver, oxide of mercury, chloride of soda, and a variety of similar applications, seem, in some degree, to act in this manner, and some of these have their action much improved by the addition of caustic alkali. Of these preparations the chloride of soda, except under particular circumstances, is much to be preferred, for whilst it seems most thoroughly to decompose and combine with the morbid secretions, it has apparently no influence on the vascular, or more vital part of the body, and therefore its application is almost unattended with pain. It is possible that there are discharges which might be destroyed by substances which have an affinity for oxygen, in which cases proto-sulphate of iron, certain vegetable preparations, as gum, sugar, &c. would be well adapted. Perhaps it is in these cases that certain balsams, as of Peru, cleanse a sore after every other local application has failed: but we must recollect that this hint, though worthy of consideration, is merely at present an hypothesis.

All local applications, however, cannot be comprised in those that act upon puriform discharge in that manner: there are some that seem to dissolve it, as chloride of zinc; there are others which arrest aqueous discharges, as acetate of lead; others which resist the action of the discharge on surrounding tissues, as lard, spermaceti, &c. Besides all these, there are others of stimulating or cooling nature, which, however, are seldom required for syphilis; unless indeed it be complicated with inflammation and its consequences, into the treatment of which it is not my present business to inquire.

I have already communicated all that is really worth knowing about this mode of treatment, yet varieties of the disease, either in degree or duration, differences of age and sex of the patients, their habits of life or idiosyncrasy, have yet to be considered; but perhaps all these circumstances will require years for their full development.

As a general rule, most patients labouring under syphilis, except, indeed, it be a sloughing phagedena, violet inflammation, or some such analogous case, no matter what form or duration, primary or secondary, provided the party be otherwise robust, or

at any rate, not in very ill health, will be benefited by the antimonial treatment. The medical man begins, if necessary, by ordering an aperient of colocynth, jalap, black draught, or similar purgative, and then directs the patient to take from 20 to 60 drops (30 medium) of antimonial wine, or the solution of antimony, every two or three hours regularly, and in every case where pus or a puriform discharge exists, use at the same time a lotion of chloride of soda, the strength of which should be regulated to the sensitiveness and delicacy of the part of the body affected.

This treatment I have seen to be efficacious in arresting the progress of the disease at the very commencement, when nothing appeared but four or five little red spots, which produce consequences, when left to their own course, that every surgeon well knows. In these cases the antimony should be used for three or four days, or even a week, till all redness and lividity are quite removed.

In simple sores, either of the prepuce or glans, the treatment is extremely efficacious, and here had better be conjoined with a solution of chloride of soda, containing about an ounce of the latter to a pint of water, which should be applied two or three times the first day. In many cases, in twenty-four hours the character of the sore becomes changed; the surface is no longer covered with white pus, a healing edge begins to show itself, and the sores, perhaps three, four, or more, are speedily healed. As soon as the character of the sore is changed, the part had better only be dabbed once or twice a day with the lotion, and at other times simply covered with a piece of dry lint; for we may be sure that here, as in all other cases, too much disturbance of a healing part only interferes with the natural healing process. Superficial sores will frequently, although of three weeks' or a month's standing, be healed in four or five days; but it is prudent to continue the antimony till not only the surface of the skin is not in the slightest degree raised, but even till the part affected assumes its natural colour.

The treatment of indurated sores is similar in all respects to that of superficial sores, and indeed that slight puffiness always to be seen round the

most superficial sore is perhaps to be considered as a slight induration, and the dense cartilaginous hardness which occasionally presents itself is nothing but the same thing differing in degree rather than in kind; and we have the authority of some most eminent surgeons, in confirmation of universal experience, that either produce indifferently secondary symptoms. The rapidity with which the cure is effected in these cases is proportionate to the degree of hardness. If the induration is moderate, the sore may heal, but the induration will remain; in which case the person is by no means to be considered as cured, for the antimony must be continued not only till the sore is cured but till the induration is removed. If the induration is very intense and hard, the sore, although healthy, will not heal till that is absorbed. In all these cases the antimony should be given very frequently at the commencement, and with the utmost regularity; for the remedy always produces the greatest effect on its first administration, and seems rather to lose its power after many days, for which reason it should be gradually increased in quantity.

Phagedenic sores generally occur in poor weakly constitutions, and require peculiar treatment on that account. The employment of antimony in these cases acts decidedly as a mild tonic; but still, as its excreting effects seem to exceed its tonic powers, we find it advisable in these cases to conjoin the use of the remedy with that of other more potent tonics. If, indeed, the skin is cold and clammy, we should use such remedies as experience has taught us determine the blood to the surface, for a few days previous to the employment of the antimony. A grain of sulphate of quinine may be given twice or thrice a day. A grain of proto-sulphate of iron, or a grain of sulphate of zinc, may be used with great advantage for the same purpose; and the antimonial drops exhibited as before. If the patient is but slightly feeble we may begin at once with the following mixture:—

R Zinci Sulphatis, gr. v.; Aquæ Dist. ʒss.; Vin. Ant. Pot. Tart., ʒss.; quaque ʒss. vel ʒj. pro. dose 2da vel tertia hora sumenda.

Proto-sulphate of iron may be substituted for the zinc with similar suc-

cess. If the patient is restless or sleepless, or the nervous system much affected, the addition of about twenty or thirty minims of syrup of poppies, or a few drops of laudanum to each dose, is of much service. A little Dover's powder may be given at bedtime. Whenever iron is employed it appears to be essential that the metal should be in the state of the protoxyd; for probably the persalts have but very little action on the system, and even that little action may be dependent upon a portion of the salt giving up one equivalent of oxygen. The nature of the salt of iron, provided it be a proto-salt, does not seem to influence the result.

In all cases where the patient is feeble, he should be desired, immediately he leaves his bed in the morning, to rub his entire body with a coarse towel till the skin is red, which will further help to promote a proper flow of blood to that important organ.

Buboes give way to antimony perhaps more rapidly than they do to mercury, and a more favourable prognosis may be given if this treatment be adopted. It would, however, be vain to attempt the removal of an inflamed bubo containing a large quantity of pus, by any general means.

Various eruptions of the skin, the sequelæ of syphilis, as a general rule, yield favourably and rapidly to antimony.

Ulcerations of the pharynx, uvula, and roof of the mouth, yield rapidly to this line of treatment. It is a good plan to use a gargle containing from ʒj. to an ʒj. of chloride sodæ to the pint of water, as that much facilitates the favourable termination of the disease. The ulceration, in these cases, rapidly loses its white layer of pus, frequently mistaken for lymph or sloughs; and as soon as a perfectly healthy surface is established the ulcer heals as rapidly as a common sore.

Ulcerations of the corners of the mouth and tongue, and a peculiar growth of the papillæ of that organ, yield rapidly to this line of treatment.

Syphilitic affections of the testicle, rhagides digitorum, &c. yield rapidly to this plan.

Of the value of antimony in syphilitic iritis and nodes I do not happen to have had any experience.

Such is a rough and brief sketch of

the cases in which antimony has produced such good results; and if we compare this remedy with mercury we shall perceive that it is entitled to the preference, in all cases in which it is applicable, and this for several reasons. In the first place, mercury takes two, three, four, or more, days before its general excretory effects manifest themselves; and previous to that time a marked and powerful stimulating effect is produced. The period of its excitement might be justly called the exciting period. This excitement, or stimulating property, increases from the commencement of the administration of the mercury till the period of salivation, just before which it is at its maximum. The exciting period is always shorter, but more violent, in direct proportion to the amount of mercury; and if very small doses be given the period is probably prolonged in length, but diminished in violence; and sometimes, in these cases, it is barely distinguishable. If two grains of calomel, and a third of a grain of opium, be given every six or eight hours, the effect is at its maximum on the second or third day, whilst its excretory and absorbent properties begin to manifest themselves on the third or fourth day. According to this view of the case, mercury given in large doses does harm to the patient on its first administration, gradually increasing the symptoms until it reaches the maximum excitement, when the same remedy alters its effects, and causes absorption and excretion. This fact is invariably seen, either in iritis, inflammation of the lungs, or peritonitis, when treated by this remedy; and hence arises the frequent necessity for bleeding before the administration of the remedy, and the frequent apparent, and even real, necessity for its repetition, either general or local, at the maximum excitement. In practice we should endeavour, as far as circumstances will permit, to cheat the remedy of this baneful effect by introducing it very gently and carefully into the system; and we find that nearly every case will yield to such a gradual administration of the remedy. In some degree the excitement is governed by the nature of the mercurial compounds, the oxides appearing to act more gently, and with less stimulation, than the chlorides, &c. Whether the remedy is taken in by the stomach, the skin, or

by fumigation, it does not seem much to matter; by the former mode, however, the effects of the remedy are far more easily controlled; for the absorption of the remedy by the latter is uncertain in amount. Sometimes the combination of small quantities of antimony with the mercury lessens the degree of excitement. The evidences of the exciting period being at hand are, additional pain, heat and redness in the inflamed part, but more especially by a large increase to the deposition of lymph, and a considerable additional impairment of the function of the organ. Moreover, the system is much disturbed, the patient is restless, sleepless, feverish, and generally in a most uncomfortable state. As the intensity of salivation and absorption are directly proportionate to the intensity of excitement and stimulation, it would be unwise, when we thoroughly understand the nature of this excitement, to lower the system by an abstraction of blood, if that can possibly be avoided.

If antimony be compared with mercury in the above properties, a vast difference is seen between them; for the first remedy appears to excite excretion within two or three hours of its first administration: the effects of mercury, however, gradually increase with the administration of the medicine, which appears to accumulate and remain in the system, whilst that of antimony seems, by long continuance, to lose in some degree its power, requiring an increase of the dose. If we look at the unpleasant effects of mercury, its salivation, destruction of the teeth, sloughing, erythema, &c. the contrast is also most striking; for I never saw antimony, in any case, produce poisonous symptoms, whilst every surgeon, even of but limited experience, must have seen frequent cases of death from the use of mercury, and sometimes even from very small doses.

The comparison between the action of tartarized antimony and iodide of potassium I feel hardly in a condition, at the present time, minutely to consider; but there are many unpleasant effects of this too-much-hackneyed medicine on the mucous, and perhaps even on the serous membranes, and, moreover, the remedy seems to remain in the system for a long period.

The treatment of syphilis by tartarized antimony, if compared with the

pil. panis systems of some modern surgeons, is most remarkable. I once had the opportunity of observing the latter practice upon a great variety of cases; and the duration of the disease appeared to be, as far as could be judged, more than treble, quadruple, or even a much higher multiple of the time required when moderate doses of mercury were administered. When, moreover, we consider that the antimonial, as a whole, may be considered more favourable than the mercurial treatment, the difference between bread (*i. e.* doing nothing) and antimony is remarkable.

The use of tartarized antimony is even more conspicuously shown in the middle than in the lower classes of society; for in the former cases the excreting apparatus is far more easily set in action, from which cause rather smaller doses may be administered: and it is a fact well worth recording, that antimony has a much greater tendency to cause vomiting or nausea in the morning than at any other period, for which reason the dose may be reduced to one-half at that period. The plan of treatment which appears to be most eminently successful is that by which a large quantity of the metallic salt is introduced into the system without any immediate effects by the means of its introduction.

The diet of the patient must be modified according to circumstances: a spare diet, as a general rule, is to be preferred, without spirituous liquors of any kind; but if the patient be feeble, nourishment or stimulus must be given, and there is no object in materially depressing the patient's strength in any case, though it would be advisable to keep him below what is termed rude health.

To ascertain the effect of antimony in entirely removing the syphilitic virus and preventing secondary symptoms, will necessarily be a work of time; but when we consider that antimony is a most potent remedy for removing the sequelæ of syphilis, how forcibly is the probability of a complete eradication of the disease presented to our minds. There are some creatures, indeed, who, unmindful of the lessons they learn, receive contagion upon contagion. In these cases we can easily conceive, that when a second or third disease is caught before the first is healed, and superimposed upon it, and the patient is

always incurring fresh risks, that some portion of the sum of all his distempers would lurk about him for ever.

The principle of the employment of tartarized antimony is probably the removal of the poison from the system, and whenever any offending matter has to be removed from the human body, the general plan of treatment for syphilis is admirably adapted. For all forms of serofula, where the matter may be regarded as a poison formed, thought not taken into the system, it is invaluable. In all forms of impetigo and encrusted sores of every kind, which are quite analogous to serofula, the rapidity with which such a treatment effects a cure is truly marvellous. Exaggerated cases of herpes yield with extraordinary rapidity, ten days or a fortnight being sometimes sufficient, in cases where the duration of former attacks had been two or three months, to effect such a complete restoration of the normal functions of the skin, as to leave no signs of a disease having existed. Sometimes a furuncular diathesis, where there is a great tendency to boils over the whole body, yields to such a line of treatment, when all other plans have failed. Even in cases of affections arising from the absorption of other metals, the treatment is of much value, for I lately had a case of paralysis agitans from the absorption of mercury which yielded steadily and rapidly to antimony and tonics.

In studying the effects of antimony upon syphilitic patients it has been complicated as little as possible with the exhibition of other medicines, yet in practice it would be folly for the surgeon to confine himself to any particular plan of treatment, but at all times, and in every case, to conjoin such remedies with the antimony as the surgeon may consider would alleviate the patient's pain, cut short the disease, or contribute to his safety. Experience, indeed, has hardly sufficiently warranted an assertion that mercury may be entirely abandoned in all cases, yet it is by no means improbable but that it may ultimately turn out that every case of syphilis may be successfully treated without it.

7, Finsbury Circus,

SURGICAL CASES.

To the Editor of the Medical Gazette.

SIR,

SHOULD you think the enclosed cases of sufficient interest, they are quite at your service.—I am, sir,

Your obedient servant,

GEORGE MAY.

Reading, Sept. 6, 1842.

Amputation at the shoulder joint.—The first case admitted into the Royal Berkshire Hospital after its opening, May 1839, was George Early, aged 15, with compound comminuted, or *open* fracture of the left humerus, close to the shoulder-joint. It had been crushed by a railroad waggon about two hours before admission.

Having recovered from the shock, immediate amputation was performed. The soft parts were much injured, and the bone fractured so high, that it was deemed needful to disarticulate. This was ably performed by the late Mr. Samuel Young, the senior provincial surgeon of the hospital.

The best flap was made which the circumstances permitted, the case progressed favourably, and he was discharged well, about nine weeks after admission.

I hope to be pardoned in obtruding here a brief tribute of respect to our lamented colleague. With mild and unobtrusive manners, with untiring devotion to his professional duties, and undeviating rectitude of conduct, he secured the friendship and esteem of his contemporaries, and enjoyed a large share of public confidence and support.

Fracture of the neck of the scapula from muscular action.—Miss M., aged 16 years, May 1823, while throwing a necklace on her neck at the toilet, screamed with pain in her right shoulder, and her arm fell disabled. The shoulder was flatter, and the head of the os humeri felt more inwards, than its fellow, the coracoid process being on a lower plane; a distinct crepitus was felt; the acromion, humerus, and clavicle, were entire. Elevation of the arm removed the deformity, which was reproduced on withdrawing the support. A pad was placed in the axilla, and the arm raised and kept to the side; passive motion was commenced at the end of six weeks, and she recovered its perfect use.

The learned author of the article *Fracture*, in the *Cyclopædia of Surgery*, doubts the existence of fracture of the neck of the scapula, but if this was not a case, I cannot understand what it was. It was not dislocation, as proved by the restoration of the shape of the parts on raising the arm, and the return of the symptoms on withdrawing the support. The humerus, acromion, and clavicle, were not injured, and the crepitus was very distinct when the coracoid process was pressed upwards and backwards by the thumb, the fingers being placed below the spine.

I presume there must have been fragility in this case, and that the fracture was produced by the sudden jerking action of the biceps and coraco-brachialis, during a frolicsome swing of the necklace. The comparatively slight deformity might have arisen from the integrity of the ligament described by Sir Astley Cooper, and the perfect recovery would warrant the presumption of union by bone.

Fracture of the head of the humerus.—David Beedle, aged 15, shoemaker, fell from a ladder, May 1820, striking his left shoulder against the edge of an area step; a portion of the humerus at its outer side was fractured, and was readily detected. It did not unite.

Aug. 1842.—The general appearance of the arm is similar to its fellow, but the head of the bone is felt to be flatter: he is occasionally inconvenienced by the broken and loose portion, but it does not materially interfere with his occupations.

Dislocation of the humerus into the axilla (the dislocation downwards of Sir A. Cooper; subpectoral, Velpeau; sub-coracoid, Malgaigne).—J. Nash, aged 49, farm labourer, came into the Royal Berkshire Hospital, March 14, 1842, having fallen from a waggon against a bank, and into a ditch of water, and dislocated his left humerus into the axilla. Being very wet and cold, he was put into a warm bath, and soon after laid on his back, and traction made by the wrist directly upwards, and in the axis of the body. The reduction was easy and immediate. If the chief obstacle to the reduction of this dislocation be the supra-spinatus muscle as stated by Sir Astley Cooper, the mode introduced by White, revived by Malgaigne, and sanctioned by Velpeau, would seem to be the most appro-

priate, by securing its complete relaxation.

Atrophy of the right deltoid muscle from injury of the circumflex nerve.—W. Emma W., aged 20, when three months old, fell from the arms of her nurse, but before reaching the ground was caught and suspended by the arm, which was disabled: she suffered considerable pain, and did not regain its free use. At the present time, Sept. 1842, the shoulder is small and flat, the head of the humerus felt as if covered only by integuments; all the other muscles are well developed, nor is there other appreciable injury: the entire arm is less than its fellow; she is unequal to over-handed exertion, and cannot bear a prolonged use of her needle, unless the elbow be supported. I think it a reasonable presumption that the circumflex nerve was injured, and that atrophy of the deltoid is the result*.

Fracture of the coronoid process of the ulna.—Blay, aged 9 years, August 1834, stumbled over a heap of stones, while running, and fell on the right hand, which was extended to save himself. The elbow-joint had the appearance of dislocation backwards; its natural shape and position were restored by flexion, but the distortion returned when the arm was extended; the humerus was broken; crepitus could not be felt.

Treatment.—The fore-arm was kept in extreme flexion, and slung around the neck; passive motion commenced at the end of five weeks, and the recovery was perfect. I think the presumption is in favour of ossific union; if by ligament, it must be very short, as it does not entail the slightest inconvenience.

Sub-luxation of the head of the radius from disease.—Ann Clarke, Reading, aged 44. Her right arm was natural at birth; when twelve months old she had small-pox, followed by abscesses in the fore-arm and elbow-joint. Present state: the head of the radius is sub-luxated backwards, and is very prominent; the arm is shorter than its fellow; the forearm semi-flexed; the hand habitually prone; supination and extension are incomplete. In this case it is probable that ulceration of the ligaments existed, and the arm being kept too long in pronation, the radius

* See observations by M. Blandin, *Continental and British Medical Review*, vol. 1.

was dislocated by the action of the biceps.

Congenital luxation of the radius backwards in both arms.—Ann Bathe, aged 16, of delicate strumous habit, has a dislocation of the radius backwards in each arm. Her mother noticed the deformity within a few days of birth, and reports her labour to have been natural, quick, and without interference. Present condition: both arms are habitually in semi-pronation and semi-flexion; they admit of complete flexion, but extension is incomplete, and supination very imperfect; the forearms are full sized, and developed proportionally to the rest of the body; the carpal joints are perfect; the head of the radius is very prominent in each arm: in the right, the superior extremity has its natural hollow, and is placed behind the outer condyle of the humerus, and reaches within half an inch of the summit of the olecranon; in the left it is rounded, and without hollow, larger, and ascends nearer to the point of the olecranon; both admit of rotation only. Each radius is obviously longer than natural, but whether its capitulum be defective or not, cannot be ascertained. The history of the cases recorded by Dupuytren and Cruveilhier being defective, their nature was a subject of speculation; the former contended for their congenital origin, the latter in favour of their being unreduced dislocations, but not congenital. The present case is positive and indubitable, having been recognised by the mother, the nurse, and others, within a few days of birth.

In Mr. Bransby Cooper's edition, Sir A. Cooper has recorded a case of accidental dislocation of the radius backwards, which occurred under my observation, with the particulars of which I furnished him at the time.

RETENTION OF URINE FROM AN HYDATID CYST.

To the Editor of the Medical Gazette.

SIR,

As I think the accompanying case is of rare occurrence, I shall feel obliged by your giving it insertion in your journal.

Yours obediently,

REGINALD JAMES,
House Surgeon.

Westminster Hospital,
Sept. 28, 1842.

On the 17th of July, Thomas Crane, ætat. 59, was admitted under the care of Mr. White, with retention of urine, not having passed any in a stream for thirty-six hours. The bladder appeared greatly distended, reaching quite as high as the navel. Skin hot and dry. Pulse 108. Was immediately placed in a warm bath, and a catheter passed. Some urine flowed, although the catheter was not in the bladder; but it went quite to the neck. Ordered

℞. Castor Oil, and ʒss. of Laudanum.

Hot fomentations to the hypogastrium.

July 18th.—Bowels had been freely moved. Catheter passed just as before, but not so much urine escaped.

Liq. Opii Sed. ℥xxv.; Aq. Pimentæ, ʒj. stat.

19th.—The bladder greatly distended. No urine escaped on passing the catheter. In great pain, and quite delirious. Ordered,

Tr. Opii, ʒj. Mucilag. Amyli, ʒij. as an enema, and Liq. Opii Sed. ℥xxv. by the mouth.

In the evening was greatly relieved by the opium, and perfectly tranquil, but no urine had passed.

20th.—Although a little urine had dribbled away, the swelling was not diminished.

V. S. ad ʒxij. and repeat the anodyne.

21st.—Not having passed any urine, and suffering severe pain, Mr. White determined to cut into the bladder. The patient was placed as in the operation of lithotomy; the incision made as in the lateral operation; but some difficulty was experienced in cutting into the bladder, from its altered position. When the bladder was divided about a pint of urine escaped; but the distension above the pubes was not diminished, nor was the pain at all lessened. After he was removed to bed, a little urine dribbled away. In the evening he became comatose, and died on the following day.

Post-mortem.—Externally, the abdomen presented much the appearance of a woman far advanced in pregnancy. On opening the cavity of the abdomen, the bladder was found greatly distended, and above it a tumor, having the appearance of a second bladder. It was firmly attached to the upper part of the bladder, and less so to the omentum. On dissecting out the tumor, it was found to be a sac, containing at least three

pints, filled with hydatids; some the size of marbles, others as large as pullets' eggs. This had so pressed the bladder against the pubes, as to divide it into two portions; one above the pubes, and rather overlaying it, and the other below: so that, when the bladder was punctured, only that urine escaped which was in the lower part of it. The portion of bladder above the pubes contained more than two pints. The obstruction to the catheter must have been caused by the displacement of the bladder, as there was no stricture in the urethra. The bladder was healthy, excepting a small spot of ulceration on the posterior part. The prostate gland was but little enlarged.

MEDICAL GAZETTE.

Friday, October 7, 1842.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medice tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

ON MEDICAL EDUCATION.

THE improvements in the system of education which have been effected within the last few years are not more apparent in any science than in that of medicine, both with regard to the period which is allotted to it, and the course which is pursued in it. Not only are the facilities of obtaining information increased in a very great degree, but the method of employing them has undergone a remarkable change for the better. With the improved opportunities to advance themselves in the science of medicine, there has been infused into our students a stronger desire to profit by them, and a greater zeal in the pursuit of knowledge. The facilities to study, and the desire to obtain information, which are by no means necessarily concomitant circumstances, and, in fact, often hold an inverse ratio to one another, have, in this instance, gone on advancing, as it were, *pari passu*. It would be absurd to pretend that this influence is uni-

versal in its operation, or to say that all partake equally of the desire to advance themselves. We need not look far to learn that all who enter the field of medicine are not hard labourers, that all are not equally anxious to cultivate the soil to its fullest advantage, and to discover the hidden treasure which lies beneath it. But we do say that no one who is acquainted with them as a body will deny that the medical students are a greatly improved and an improving class.

The higher rate of knowledge with which the generality of practitioners now commence the duties of their profession, in comparison with that of their predecessors, is alone sufficient evidence of this. In thus speaking, we throw no disgrace upon the seniors of the profession—we desire to institute no invidious comparisons. In stating that the average amount of knowledge with which they left the schools and entered upon their practice was inferior to that possessed by the graduate of the present day, we cast no reflection upon the industry of the one party, and show no superiority of merit in the other. The difference between them is not to be referred to any distinguishing feature in either, but simply to the period in which each lived, and the advantages which each enjoyed—to the greater facilities of information which the student of the present age possesses, and the improved system under which he has the good fortune to come, in comparison with that under which the student of thirty years ago was placed.

This improvement cannot be traced to any one cause, but is owing to a combination of circumstances, and has been slow and gradual in its progress. Among other things, it may be, in part, attributed to that march of intellect, or general advance of science and education, which has characterized the late period of peace and prosperity in

our country, and has extended its influence to medicine as well as to every other branch of science. It may also be in part attributed to a spirit of emulation arising between the teachers as well as between the students in the different schools, which now exist in such numbers that the supporters of each are obliged to labour hard to maintain its reputation. Thus has sprung up a rivalry between the various provincial and metropolitan schools which has tended to the improvement of them all. Emulation among students has, in various ways, been encouraged and turned to good purpose, especially by the distributions of prizes and honorary distinctions, which take place in almost every school, as well as by the various offices and appointments which are bestowed according to merit.

It would be an injustice to the regulating and examining boards of the profession to omit to mention the assistance which their endeavours have contributed in promoting this advance in the proficiency of students. By the judicious alterations in the course of education which they have introduced, especially with regard to the apprenticeship system—by curtailing that period of which so large a portion was wasted on the manual drudgery of the profession, and permitting a more extended routine of study in London, or some large provincial town—they have done great service to the profession. By requiring certificates of the attendance on certain courses of lectures, and of a given routine of dissection and hospital practice, they have enforced the opportunity of a wider and more regular course of study. They have regulated the employment of that period in a methodic manner (we will not say in the *most* advantageous manner); and by their stricter examinations, they have required from the candidates for their diploma a higher rate of knowledge.

These and a variety of other circumstances, which it is needless to mention here (for we do not pretend, neither would it be an easy task, to enumerate them all), have conspired to render the rising practitioners of the present day a better informed class of persons, and more fit to undertake the important duties of their profession, than could be the case in days of yore, when the student had neither time nor opportunity given him to acquire more than the rudiments of medicine, and was hurried into practice to gather up, as he went along, the information which his own observation might furnish him. And it is not simply in a scientific, but in a moral point of view also, that we flatter ourselves improvement has been effected. The medical student no longer merits that character which it has been his lot to possess in comparatively recent times, and which was attached to him by a modern writer with no sparing hand. An evil reputation once stamped is long in wearing out, although the cause which impressed it may have ceased to exist, and the bearer become undeserving of it: and so it has been with medical students; they still endure, to a greater or less degree, the opinions which were formed of their predecessors, and which are probably no more applicable to them than to any others.

There is, moreover, another thing which is of comparatively recent existence in medicine, but which is daily gaining ground in the large metropolitan schools, and has already done something to assist in improving the cast of medical students, at the same time that it bids fair to effect much more—we refer to the system of private tuition. We are aware that some objections are urged against it on the ground of its increasing the expense of medical education, and giving to those who can afford to avail themselves of it an unfair advantage over their poorer brethren, in competitions

for honours and appointments which are made the reward of merit. Even granting that these objections are valid, and some others of less moment which are brought against it, we still maintain that the general good effect of such a system, if brought fairly into operation, would be very great, and it would tend, in various ways, farther to improve the character of students, and, by its influence on them, to advance the science of medicine.

Let us look at the Universities of Oxford and Cambridge, where a plan of this sort has been long and extensively carried out, and has even, in a great degree, supplanted the professorial mode of teaching in classes. It is a well-known fact that almost all who are desirous of taking even a respectable station, much more those who are ambitious of obtaining a high rank in the examinations, have recourse to a private tutor, whose advice and close superintendence they well know is more likely to ensure their success than the regular and more formal instruction of the college lecturer or the public professor. Very few indeed carry off the high honours in the university without having recourse to such assistance in their studies. Here, then, the tutorial system, as it has been called, has received a full and fair trial, and no other proof of its efficiency need be given than the extensive manner in which it has been here adopted.

It may perhaps be said that private tuition is less important in the study of medicine, where the books are easy, and observation and experiment are the principal guides, than in the study of the dead languages, or in the abstruse processes of mathematical reasoning: and we grant, to a certain extent, the truth of the assertion. But, though it may be less in degree, its effect is nevertheless good. The opportunities of supervision and direction afforded by it are such as can be ensured in no

other way, and such as are truly wanted by the generality of students, who, coming up to the schools, are plunged in the whirlpool of lectures, dissecting and hospital practice, scarce knowing which way to turn, or where to begin. They have no one to direct their studies, and are ignorant what subjects to commence, what books to buy, or what order to follow. They enter upon their studies, perhaps, with ardour and good determination; but their endeavours fail, like the aim of the unskilful marksman, for want of proper direction; they become disgusted with the little progress they make, throw aside their books, and betake themselves to other, not usually more profitable, amusements; such, at least, is too often the case. They are still less under any moral discipline, and, turned loose into the world, are too apt to fall an easy prey to the temptations around them.

A careful system of private tuition would, no doubt, prove a powerful remedy to many of these evils: the employment of the pupil's time would be superintended, his studies directed, and a gentler or less influence exerted over his moral life. Such a system would probably in time give a most effectual check to the obnoxious process of mere *grinding*, and would form of itself a far more profitable substitute; at least it certainly appears to us that it would be more likely to benefit the student than the ordeal of cramming, which, *volens volens*, a vast number deem it their imperative duty to undergo.

We throw out these hints just now on this subject, thinking they may be of service to some who are about to enter upon their medical education in London or elsewhere, with the commencement of the session, and who are in doubt as to what course they had better adopt to turn their time to the most profitable account. We would recommend them to give the subject a careful consideration and should they

adopt some such course as we have advised, they will not, we think, have any reason to regret the step they have taken—if, at least, we may judge from the opinions of those who can bear witness to the practical effect which it has had on themselves, of whom we never heard any speak but in terms of the highest satisfaction, of the advantages which they derived from it.

INSPECTORS OF ANATOMY.

WE announced last week the appointment of Mr. Alcock and Mr. Bacot, as Inspectors for England: we have now to add, that Dr. Andrew Wood, of Edinburgh, has been appointed Inspector for Scotland.

INTRODUCTORY LECTURE,

Delivered at University College,

Oct. 1, 1842,

By C. J. B. WILLIAMS, M.D. F.R.S.

Professor of the Principles and Practice of Medicine, and of Clinical Medicine, &c.

State of practical medicine, as a study, and as an art—Insufficiency of empirical and nosological medicine—General pathology the true foundation for practical medicine.—What is general pathology?—Its relations to clinical medicine—Noble nature and objects of medicine.

I HAVE been requested by my colleagues to open the business of the session; and in doing so I shall adhere to our usual practice, by making the subjects of this address also introductory to those of my own course.

It is three years since I gave my first introductory lecture in this place; and when I recollect the trembling anxiety which I then felt at the prospect of the difficult and responsible duties which devolved on me, my heart fills with gratitude to a Gracious Providence who has granted me health and strength of body and mind to perform these duties, however imperfectly; and I cannot forget the kindness of my pupils in overlooking the faults and deficiencies of my first attempts.

Now, at the commencement of a fourth session, I hope I need not say that my sense of the importance and responsibility of my office is in no degree diminished. Nay, it is much increased. The longer a medical man practises his profession, the more he sees the value of a right knowledge of it; and, if his conscience be not seared, the more anxious will he, who teaches, be to communicate that right knowledge to his pupils. Further, time and experience ought to improve the resources and strengthen the faculties of the teacher, and give greater weight to his opinions: in like proportion also should he feel responsible for the in-

creased influence which he may exercise over the minds of his hearers.

I must further state another circumstance which greatly upholds my anxiety to bestow my best exertions in teaching the subjects of my course. It is *the low position which this most important part of medical science still holds with the public, and even with students.* I feel this to be a matter of such moment, that I propose to make the chief subject of this lecture, the state of practical medicine, as a study, and as an art.

Compare the state of the practice of medicine with that of anatomy, physiology, and chemistry—the great fundamental or preparatory studies. How minute, how precise, how connected and definite are these! Yet how loose, indefinite, uncertain, unconnected, is the practice of our art. To the public it appears altogether vague—without any acknowledged principles.

Is there any wonder, then, that quackery should triumph; that the public show their want of faith in legitimate medicine by their ready belief in any novelty that is not legitimate? Thus, one year, St. John Long's plan; another year, homœopathy; another, Morison's pills; another, the water-cure—rules the fashion. The public may show their ignorance by such credulity; but they show also the want of something plain and trustworthy in regular medicine. The public will not believe that the secret of the art is with a faculty which professes to follow experience only. The quack also can appeal to his experience; and that, too, in a way more striking and convincing than those who express doubts and admit difficulties. Thus one who cures nervous diseases can calculate his success by the numerical method. In 8000 cases he can count only 20 failures. Another tells you of an extraordinary percentage of success in cases of deafness, in which the *most eminent practitioners had failed*, &c. Hence you will find the partisans of quackery far more zealous in the defence of their favourite notions than others are in support of the regular art. No wonder that homœopathy and the water-cure have their royal and noble advocates. Then there is a captivating simplicity in the theories of quacks. A certain high official personage pins his faith to an empiric who was formerly a gardener, and whose notion is that all diseases proceed from buttercups. This is the theory: every man, woman, and child, eats mutton, beef, or butter, or drinks milk: every cow and sheep eats buttercups with its grass: buttercups are rank and acrid weeds: *ergo*, all diseases proceed from buttercups. How beautifully simple! How attractive, too, are the comprehensive views of the hygeist and the water curers! they both agree in their pathology; all diseases arise from bad matter in the blood; they only differ in their mode of expelling it from

the system. One purges out the peccant humour; the other washes and sweats it forth. There is something, too, very fascinating in the notions of homœopathy: *similia similibus medentur*. Who cannot fail to admire the expansive genius of Hahnemann, who discovered that the best cure for a disease is the influence which caused it?

On the other hand, the regular practitioner has nothing so plausible or so captivating to bring forward in explanation of *his* method. He either has no theory at all, and grounds his practice on experience (in which we have said he is matched by the empiric), or, if he gives a theory, it is viewed only as an opinion no better than the hypothesis of the quack, in an art so little founded on principles as medicine. So little favour does medicine receive from the public in its pretensions to science!

How is it with the student? Surely the practice of physic must be as interesting as it is important to the student—the useful application of all his knowledge—the wind-up of the drama of his studies—the rehearsal of the great performance of his life. Surely this must be a very attractive study? Quite the contrary. I believe it has been generally considered by students as the heaviest, most repulsive, most tedious of all subjects (with, perhaps, a single exception). Without the constant appeal to the senses with which *anatomy* attracts and rivets attention; without the beautiful connections and adaptation of means to ends which make *physiology* interesting; without the simplicity and striking phenomena which give a charm to *chemistry*, the practice of medicine, as taught, is an enormous mass of dry detail; its science, mere glimpses into an unknown land; its rules, irregular tracks through a wilderness of confusion. Practical medicine is studied only from a conviction that it is useful and necessary; and not because it is easy or agreeable.

Further, there are a great many students, certainly not the most industrious, who shirk the disagreeable duty, pleading that it is neither useful nor necessary; and that the practice of medicine is only to be learnt at the bedside with whatever aid books can supply. It would speak more in favour of this opinion, if its advocates acted up to their dogma, and proved, by their constant and diligent attendance in the wards of the hospital, that they seek there the knowledge which they profess to be unable to obtain in the lecture-room. But, so far as my observation has gone, I do not find this to be the case. It is not those that neglect the lectures, but those who most regularly attend them, that prove to be attentive students in the hospital.

But, although useful and necessary, it cannot be denied that the study of the practice of medicine, both by books and by

lectures, is at first very difficult and irksome: more so than other studies. But why is it so? This is a serious matter. Let us examine a little into it. Is the fault in the imperfect state of the subject, or in the method by which it is taught? The science of practical medicine is undoubtedly very imperfect; but I think it can be shown that there is a still greater imperfection in the method by which it is taught.

As anatomy and physiology, with chemistry, are the studies preparatory to medicine, one might expect that they should be made fundamental to that of medicine; that, starting from the knowledge of the healthy body, as taught by them, the transition should be easy and intelligible to disease—first, in its lowest degrees and simplest form; then to the more compound, pronounced, and more removed from, but still comparable with, the healthy standard. Instead of this, lecturers and writers plunge at once into the mazy thickets of inflammation and fever—subjects so complicated, so changed from any thing taught by previous study, that anatomy and physiology afford little help: and no wonder that the student (like many observers and reasoners on the same topics) becomes confused and bewildered in the complexity of the subject; or, if he do make out any thing, it is something isolated, abstract, about fever or inflammation itself, without its natural relations to health and to other diseases.

This plan of proceeding may be compared to a person beginning the study of mechanics with the steam engine; or to the student of chemistry commencing with organic matter.

The general result is, that, where any distinct notion of disease is acquired, it is one not at all founded on previous physiological knowledge; but it is a new idea of disease as an absolute, separate thing, not a mere condition consisting of altered function and structure, but a being, the character and history of which are to be detailed like that of a plant or an animal. And when special diseases are treated of, the same individualizing process is pursued through all the jargon of the schools. Each has its nosology, classification, and definition, its predisposing, exciting, and proximate causes, its theory, *ratio symptomatum*, its diagnosis, prognosis, indications of cure, fulfilment of these, *juvantia et ludentia*, and prophylaxis!

With all this formidable array to each disease, the practice of physic was an arduous study in the days of Cullen. What must it be now, when the diseases of Cullen's nosology have been almost doubled, and the facts relating to them have been more than doubled?

But let us follow the student, well crammed with his nosological list, their definitions, &c. to the bedside. Let us see how his knowledge, so meritoriously and

laboriously obtained, will serve him in the hour of need. In a few cases of fully developed and well-marked acute diseases, such as pleurisy, scarlet fever, or rheumatism, he may get on pretty well; but in the commoner description of cases, acute or chronic, in their early stages, in their endless variations from peculiarities of constitution, or from complicating causes, he finds himself continually puzzled: the phenomena do not correspond with any of his defined diseases: they frequently change their character in a way that he cannot account for; his prognosis is falsified; his diagnosis fails; and his treatment, although not always unsuccessful, does not answer according to his expectations; some patients recovering whom he expected to die; others dying, or not improving, whom he expected to recover.

Disappointed, in the failure of his nosological learning, the young practitioner more and more mistrusts it, and falls into a routine of empirical practice. Without troubling his head about the name or nature of diseases, he thinks solely of their treatment; and, begrudging the time that he has spent with books and lectures, he decries every thing that is not practical.

Still he is obliged to retain some notions of the theory of disease; but they are general notions, and not fettered by definitions. He still studies symptoms: he seeks in the pulse and heat of skin indications of fever and inflammation; he looks to the tongue and alvine evacuations for proofs of disorder of the digestive organs; he judges, by the complexion and muscular strength, the state of the constitution. Instead of troublesome scholastic definitions, he uses convenient, general terms, which may be taken in a pretty vague sense—such as irritation, congestion, constitutional weakness, cachexia, disordered digestive organs, scrofula, scorbutic habit, and the like; and his remedial measures are designated in the same convenient general terms—such as soothing, cooling, supporting, stimulating, alterative, purifying, &c.

In short, he has, in practice, learnt himself, in a loose way, at the expense of previous studies, and sometimes, it is to be feared, at the expense of some bad practice, what he ought to have been properly taught as the foundation of his studies—*general pathology*. Thus we are led to the presumption that general pathology is the proper basis for practical medicine; and I venture to affirm that a chief reason why the practice of medicine has been commonly so distasteful, and so difficult in its study, and so unsatisfactory when tested at the bedside, is because its foundation, *general pathology*, has not been efficiently taught.

We have just met with a practical illustration of the truth, that general pathology

is a more efficient help at the bed-side than such knowledge of diseases as is to be obtained only from nosological definitions and details. Before I proceed to exemplify this truth, by matters of every-day experience, let me first briefly point out why it is so.

Without the connecting link of general pathology, practical medicine derives little or no aid from anatomy and physiology. Instead of being founded on them, it is studied and practised quite independent of a full knowledge of them, and is generally acquired in proportion as they are forgotten. This kind of practical medicine is much the same as that of old women and nurses; it consists chiefly of treating symptoms, or groups of symptoms (called diseases), by remedies that have been found useful in similar cases, without the trouble of inquiring about the causes of the symptoms, or the precise seat of the disease. Thus, if a person complains of headache and giddiness, leeches are applied, purgatives are given, because they have been found useful in similar cases. An intimate knowledge of the structure and functions of the contents of the head would give no further help in the use of these remedies; nor suggest others if these be found to fail. If they do fail, the only resource is in experiment: first one thing is tried, then another, until much mischief may be done, or at last, perchance, the right remedy may be hit upon; and this may be the very opposite of those first used. Long experience may make the symptom-treating practitioner more successful, if he be an observing man; because it will acquaint him with additional symptoms to be considered for the guidance of the treatment. But there are few of this class of practitioners who are carefully observing men, who do remember and profit by their experience: they more generally, like their sisters, the nurses, keep pretty close to their first notions; and although age and the name of experience may screen *their* failures, alas for the young adventurer who sets sail on this tack!

But the benefit of such experience is gained at the commencement by the student of pathology. He has learnt to trace symptoms to their causes. Having been taught, by anatomy, the peculiarities of the circulation in the head, and by physiology, confirmed by clinical observation, that this circulation may be similarly impeded by opposite causes, inanition as well as fulness, he is prepared to find out, through other symptoms, which is the cause of the headache in the case before him; and he adapts his remedies accordingly.

In fact, a true pathology, or sound principles of medicine, is the embodiment of the result of experience in disease, with a knowledge of structure and function in health. It is the only connecting link between the preparatory sciences and practica

medicine. *Without* it, these are *dissecta membra*: *with* it, they form a connected body of science—young yet, it is true, and falling short of the objects of the art, but already available for much, and needing only the growth and continued support of its chief members, especially anatomy, physiology, and clinical observation, to become the perfect and efficient director of practical medicine.

The great proof of the practical utility of general pathology is the aid which it gives in the study of clinical medicine, and the light which clinical medicine continually throws on it. The states which the practitioner has to treat are often too indefinite or too mixed to correspond with any of the definitions of special disease. They frequently consist of functional disorder, varying with time and circumstance, or changing its place, so as to present no fixed characters. But, compared by the pathologist with the standard of health, and analysed from their complexity, their nature becomes intelligible, and their proper treatment obvious, so far as means are possessed to counteract or control that which is wrong. Let us take one out of many examples. The disordered state of health, for treating which Mr. Abernethy gained such a reputation, is one of the commonest ailments we have to prescribe for: some call it, with Abernethy, "all stomach;" others, "liver"; others, "disordered constitution"; others, "indigestion": but however differently they may name it, few refuse to treat it, as Abernethy did, by regulated diet, blue pill, and mild saline aperients, repeatedly administered. Now the pathologist analyses the symptoms of such a state, and in the white or yellowish-furred tongue, morbid eructations, tender epigastrium, sometimes full right hypochondrium, with extended dulness on percussion, the discoloured faces, the high-coloured and turbid urine, he finds proof of congestion and disturbed secretion of the liver and upper part of the alimentary canal; and he recognizes in the remedies employed means which, by increasing the secretions, relieve the congestion; and if these fail, he can suggest other measures which he knows to be efficacious in removing congestion, and restoring the natural secretions. Again, what confusion in diagnosis, as well as in practice, has arisen from comprehending, under the specific name *hysteria*, the most opposite and most varying conditions, merely because they are consorted with some nervous phenomena; so that this word becomes almost synonymous with *female diseases*. But, pathologically considered, the confusion in diagnosis, and, in some measure, the perplexity in regard to treatment, cease. In one group of such cases, the pathologist

finds really such signs of disordered *uterine* function as would justify the name: other symptoms, however varied, taking their origin from this disorder; and he thus discovers the necessity of directing the treatment to this cause. In another group again he finds the uterine function impaired; but this only in common with other functions; and all this in consequence of a *want of blood* throughout the body, which want is denoted by the waxy complexion, the pallid lips and gums, the loose yet easily quickened pulse, the panting breath, the feeble limbs, &c. Here the restoration of the blood is the obvious indication; and in proportion as this is effected, the symptoms of nervousness, debility, and loss of function, disappear. In a third group of cases, called hysterical, the pathologist discovers the opposite condition, that of *sanguineous plethora*, which, independently of any disorder of the uterus, causes trouble, sometimes in one part, sometimes in another, but especially in the nervous system, which, in most females, is peculiarly liable to disorder. Here, too, he is led to the most appropriate treatment.

This is but one instance out of many that might be adduced to show the great practical utility of a good knowledge of pathology. In fact, the leading rules of practice, those which guide the most experienced men, (although many are not aware of it, and would not acknowledge it), are founded on general views of diseased function and structure—that is, *general pathology*. You will not find that practical men treat a disease merely according to its name, or according to the nature of the local mischief. Inflammation is not always to be combated by blood-letting, nor hæmorrhage by styptics. The condition of the system—that is, of the functions, is to be taken into account; and the variations of this condition, the states of sthenia and asthenia, tone and debility, excitement and depression, plethora and anæmia, are the very subjects which general pathology explains and shows how to treat.

I say practitioners *do* act more on general ideas of disease than on their knowledge of particular diseases. They feel the pulse and the skin, to guide them in the use of blood-letting—whether they have found out the special disease or not. They examine the tongue and inquire as to the state of the evacuations, to guide them in the use of purgatives, under whatever complaint the patient labours. They consider the complexion and bodily strength in connection with dietetic measures; and the chief treatment of convalescence depends on rules suggested by general pathological knowledge.

There are other very important departments of medicine which are comprehended in general pathology, and with it have been too much neglected—I mean the study of the

causes of disease, and their modes of operating on the living body (*etiology*), and the means by which they may be avoided or counteracted, including *prophylaxis*, or the prevention of disease, and *hygienics*, preservation of health. Neither of these subjects can be satisfactorily comprehended without a sufficient knowledge of the elements and laws of disease.

Is it not, therefore, most important that these general views, which are so practical and so extensive in their application, should be well founded and carefully studied? Is it right that the leading doctrines of disease, leading, not in theory but in practice, should, as hitherto, be left to be picked up irregularly, from casual retrospects of study or experience, when they may be learnt as the very groundwork of practical knowledge?

What, then, is this general pathology, which we extol so much as the proper foundation of practical medicine? Let us first state what it is not. It is not a collection of hypotheses hung on solitary facts, and ingeniously devised to explain this or that symptom, or the *modus operandi* of this or that remedy. It is not any thing floating on (I can't say founded on) conjectural notions in anatomy and physiology, such as the existence and circulation of a nervous fluid, the presiding influence of the ganglionic system, or the vital attractions and repulsions of the circulating fluids; notions which, however they may hereafter be substantiated, are at present too speculative to form a foundation for pathology. Nor is it a partial set of opinions, erected on *one* only of the many peditments of fact on which the science of medicine should stand. Healthy anatomy, physiology, physics, chemistry, the study of clinical medicine, that of *materia medica*, morbid anatomy—neither of these *alone* can furnish a foundation for pathology—that foundation must be formed by *ALL*—the facts which all supply constitute the material of which it is built, and the general facts or laws of all must be brought to bear on the arrangement of these materials in the construction of a system of pathology.

Some advancement in these contributory departments is necessary before the work can be begun, and it is because they *have* advanced that the opportunity is afforded. Why should the science of medicine remain in a state of powerless infancy, when its members are progressively acquiring strength and maturity? Why should the art of medicine still be a groping about in blind empiricism, and an unintelligible confusion of facts, when science even now can afford it the beginnings of light and of order?

I have just said that the contributory sciences are sufficiently advanced to be generally applicable to practical medicine. The proofs of this in detail will, I trust, appear in the

progress of the course; but I will adduce here a few examples of a prominent kind. Disease, in so far as it is the result of *mechanical* change, or in part made up of mechanical elements, may be properly treated by *mechanical* means. It was the knowledge of this fact which led Dr. Arnott to invent that admirable contrivance, the water-bed, by which disease is often prevented and removed; and he has lately made another application of physical science in modes of applying pressure to parts with such equality as to control to any degree the circulation of blood through them, and thus to relieve pain, remove congestion, subdue inflammation, heal ulcers, disperse swellings, and arrest the growth, if not to effect the removal, of tumors and other morbid productions. Disease, so far as it is physical in its nature and in its effects, is to be investigated by physical means. Hence the advantage of acoustic science in assisting us in diagnosis of internal disease, and of optical science in enabling us to witness the minutiae of its operations and its products. I need scarcely add, that the treatment of disease is in some instances founded on, and in most cases guided by, knowledge thus obtained.

As an example of improvements in *anatomy* and *physiology* bearing on practical medicine, I may mention the late researches on the nervous system, and especially those of Dr. Hall. By these, much that before was unintelligible in diseases of the nervous system has been satisfactorily explained, and their diagnosis and treatment have received proportionate aid. Considerable light has been thrown on diseases of the liver and of the heart, by recent anatomical and physiological investigations of these organs.

The aids afforded by *chemistry* to the *materia medica* have been long acknowledged, and continue to increase; but chemistry is growing in importance in its applications to every department of practical medicine. It is now directly useful in the diagnosis and treatment of diseases of the urinary organs. It furnishes a key to the most important rules of diet, in health as well as in disease, and bids fair to supply much that is wanting in explanation of the origin of many maladies, and the most direct mode of preventing them. It is through the aid of organic chemistry, now far advanced—advanced too, mainly, by the labours and genius of an illustrious chemist who this day honours us with his presence (Professor Liebig)—that we may hope that experimental physiologists and clinical observers will be enabled to solve some of the dark problems of the operation of medicines—a subject replete with practical importance, yet one that still lies chiefly in the region of conjecture.

It will not be disputed that *clinical observation* has lately done much for the advance-

ment of the science of medicine ; and this not only because it is the test by which the contributions of other branches are tried, but also because in itself it is carried on with the minuteness and precision which are essential to science. This precision must apply not only to the modes of calculating facts, but also and most particularly to the correct determination and classification of these facts. The accuracy of counting is a mere facility in common arithmetic. The accuracy of observing and arranging the facts to be counted is the higher and rarer quality. Both are required in the prosecution of clinical research.

The whole department of practical medicine teems with examples of the benefits which it has derived from *morbid anatomy*. What should we know of the nature, products, and tendencies of inflammations and other diseases which alter the structure, but for the scalpel revealing them to our very sight and touch ? The minuteness with which it (morbid anatomy) has been pursued in connection with clinical observation, in regard to diseases of the lungs, heart, liver, kidneys, and alimentary canal, deserves especially to be mentioned as the great source of our improved theory and practice in these complaints.

It is not a general or superficial knowledge of any of these fundamental sciences that will avail to make them profitable to medicine. It is where their facts and laws have been carefully studied in relation to the living body that the advantage has become practical ; and this study has in many instances developed new phenomena, which reflect light also on the contributory science. The application of hearing to the distinction of diseases has given rise to a more intimate knowledge of acoustic science. Some of the most interesting facts and laws of organic chemistry have resulted from researches instituted with reference to the investigation of disease—as for example those of Prout, Wohler, and Liebig. In regard to anatomy and physiology, the instances are abundant. For example, the researches of Charles Bell, Foville, and M. Hall, on the nervous system, and those of Astley Cooper on the testicle and mamma, were conducted with express reference to diseases of these organs, and were often suggested by the knowledge previously possessed of these diseases. In this respect they followed John Hunter, who throughout his anatomical labours had an eye to pathology, and by observing disease, was continually guided to objects for these labours.

So we shall find, as we proceed to the details of pathology, that subjects which require further research are continually presented to us in a practicable form ; and I shall take occasion to point out some of

these, in the hope that some among you may be induced to cultivate ground which is rich in promise of important practical results.

Do not suppose, because I insist strongly on general pathology being the proper basis of practical medicine, that this will lead us to neglect the superstructure, *special pathology*. Individual diseases will be the chief subjects of the course, occupying 100 out of 130 lectures ; and I trust that their details will become much more comprehensible by the arrangement into which general pathology will enable us to distribute them. It is because I feel the vast importance and extent of our knowledge of individual disease, that I would endeavour to introduce you to it from the most advantageous and commanding position, and that position is afforded by a previous acquaintance with the general features of disease. In fact, individual diseases are like the leaves and boughs of the tree of which general pathology constitutes the trunk and great branches—all preserving an identity and connection, yet each portion having peculiarities of character which require separate study. Or medicine may be compared to a great edifice, the foundation and great entrances of which represent pathology, which generally give the proper approach to the separate rooms, special diseases. To some of these, in the imperfect state of the structure, there may be access only by the dark back ways of blind experience, which there must not be neglected ; but this is no reason for making these *dark back* ways the only entrance.

Throughout our examination of the details of disease, we shall find the principles of general pathology continually exemplified ; and through these principles the mind can master the details to an extent wholly unattainable by those who pursue them as unconnected matters of fact. Those who begin the study of practical medicine by attempting to learn the details of diseases, are like those who would endeavour to master all the facts of chemistry without any knowledge of the general facts or laws of chemical action, affinity and definite proportions ; yet even in practical chemistry, or chemistry applied to the arts and manufactures, the most extensive and important services have been obtained from these very principles, applied to the details.

But in treating of individual diseases, although we shall find our previous pathological principles of great use in explaining and simplifying the details, we are not to be tied to them whenever experience varies from those principles, or goes beyond them, —there, experience must be carefully followed. There is no subject in which this simple statement of fact is more frequently necessary than in regard to the *modus operandi* of medicines. It is quite true that

many curious speculations have been offered on this subject. In fact, it seems to be quite the hobby, or the Pegasus, of a very speculative class of men who call themselves practical. These can tell you to a nicety how mercury cures syphilis; how opium causes sleep; on what precise parts of the intestinal tube each variety of purgative acts, &c. But as in most of such hypotheses there is much more of fancy than of fact; and as the fancy, if erroneous, may be mischievous in a strictly practical matter, I shall be excused if I prefer giving you the naked matters of fact.

The purpose of lectures on the practice of medicine is not merely to convey knowledge of disease and its treatment, but also to direct the mind in the ways of using this knowledge, and of acquiring more. Books will supply details which cannot be given in the lectures; but the more important additional source of information is *clinical instruction*. This is an essential part of the teaching of practical medicine. It is its demonstrative part, and is essential, not only because, like other witnessed phenomena, it appeals to the senses, but also because it is necessary to practise those senses in the examination of the signs of disease, and to exercise the reasoning powers in the interpretation of those signs, and in the further application of previously acquired knowledge. As general pathology is the connecting link between the preparatory studies and practical medicine, so clinical instruction is the step between the knowledge of medicine and the personal application of that knowledge in actual practice. I need not say that each of these is most necessary to the formation of a good practitioner: but there are especial reasons why clinical study, connected with the practice of medicine, is more indispensable now than it ever was. In former days medicine was little more than a matter of routine, and the examination of a patient was summed up in feeling the pulse, looking at the tongue, and asking a few questions as to the feelings and functions, and this was often done for the sake more of form than of information; for the pills and draughts were much the same in most cases. This was little better than quackery, and required no great preparatory study. That it sometimes succeeded to win the favour of the public is not surprising, seeing that quackery often had a similar or greater success. Then the ignorant practitioner could disguise his emptiness by a cloak of mystery, and a solemnity of manner, and could command confidence by dropping a hint about his experience, tact, and intuitive perception of disease. But, ignorant as people still are in medical matters, they are not so dull as to be deceived by these means. They have a smattering of physiology and the use of

remedies, and they are become troublesomely inquisitive; and if they are taken in, it is by the clever quack, who is ready with his theories and persuasive proportion of cures, and not by the unsatisfactory regular, who examines but little, and cannot explain his views or his practice. In short, the public look for what they have a right to expect, thoroughly educated practitioners, who prove their qualifications by their careful method of investigating disease, the clearness with which they give their opinions, and the general correctness of those opinions.

This, then, is another reason for thoroughly availing yourselves of practical instruction, especially in the clinical department. The great importance of this department has occasioned the adoption of extended measures for teaching it. I trust that you will prove, by the assiduity and success of your practical studies, that the College has not adopted these means in vain; but that, as in the preparatory branches, so in the finishing of your medical education, you will obtain that high standard of qualification that must ensure the confidence and esteem of those among whom you may exercise your calling.

Gentlemen, we have great pleasure in meeting you again for the session—those who have favoured us before, as old friends; new-comers we welcome to the work; which, although arduous, is not one of drudgery. I almost envy the pleasure, in young and ardent minds, of rising step by step in knowledge, and delighting in the wonders and beauties of the enlarging view. I admit that the ascent is arduous—that it requires hard labour, and no little self-denial. But is there no compensation in the delight of acquiring knowledge and intellectual power? No gratification in learning and contemplating the intricate beauties of the most perfect part of the creation? Is there no moral and religious good to our own minds in tracing out and unveiling its frailties, weakness, decay, and death? No satisfaction in learning of means which a Gracious Providence supplies for preventing and removing the ills which flesh is heir to; for relief of pain, suffering, and weakness, and restoration of health and strength? And if from present studies you carry your anticipations onwards to their final object in practice—under heaven, yourselves to ease suffering humanity, and to invigorate and prolong life—is the pursuit less noble, or less worthy of your highest thought? Need I say more for the intellectual and moral greatness of our art?

Is a study noble in proportion to the breadth, and depth, and diversity of the knowledge on which it is founded? Then, think of medicine; how she levies her contributions from every branch of knowledge. The human body exhibits a machinery so

perfect, that the most skilful mechanical philosopher may take lessons from studying it. It contains a laboratory so diversified, and chemical processes so subtle, that therein the ability of the most expert chemist is far surpassed. But the knowledge of the student of medicine must go beyond that of the mechanical and chemical philosopher. He must study those vital properties, of which they can tell him nothing. He must become acquainted with the attributes of life operating in matter. In animal generation, nutrition, growth, secretion, motion, and sensation; in the variations of these processes, in their decay, and in their cessation, which is death, he has a complicated study, peculiarly his own, in addition to those of a more elementary nature. He has, besides, to contemplate the body under disease, and to bring to his aid the three kingdoms of nature, and almost every art and every science, for agents and means to counteract and control that which disturbs its well-being. But is the body the only object of his care? No. Mind and matter are too closely combined to be studied or treated apart. To medicine alone it belongs to contemplate and to treat the **ENTIRE MAN—PHYSICAL, MORAL, AND INTELLECTUAL.** What can I say more of the intellectual greatness of our art?

Neither shall I strain your thoughts far to remind you of its moral worth. See its effect on masses of mankind, displayed in the progress of the happy discovery of Jenner! See how even barbarous people and idolaters, Mussulmen, Hindoos, and Chinese, respect our nation only for the medical aid which it can supply. So that it has happened that medicine has become the handmaid of religion—a bond between countries, a peace-maker between nations.

But let us not vaunt ourselves. Listen to one who speaks of our art—and that one the eloquent ambassador from the United States, the Hon. Edward Everett. I quote from the *Times* of the day before yesterday. "For what was that which constituted the chief pride and glory of the British nation? They had heard of the intercepted letter from one Chinese chieftain to another; and what was the characteristic which had excited the admiration of the mandarin of a great and important empire, reeling at the time under the blows of the British Government? Was it the military prowess of their countrymen? Was it the steam-vessels of war reaching coasts in defiance of the desolating simoom? Was it their arms—their artillery—their skill of engineering, which civilized nations now brought to the strategy of war? Was it this, or any of these, which had struck with wonder, and awe, and admiration, the barbarians of China? No! It was the humanity of British physicians and

surgeons—their management of hospitals, and the generous kindness which was extended to the sick and wounded, even of a hostile nation—which moved them with astonishment, and excited their sympathy and regard. These were some of the arts of peace which extorted the admiration of an enemy, and which other states would do well to imitate."

But if you would see the moral influence of medicine depicted in its liveliest hues, I would ask you to contemplate a domestic scene: a family whose hearts are wrung with a dreadful anxiety for one vibrating between life and death. What a ministering angel does the physician seem! How they watch his every look! With what breathless earnestness do they hang on his words! and those words, how they wing themselves to the souls of the bearer for sorrow or for joy! Yet such scenes are passing daily and hourly in every class of society—in the mansion and in the cottage: they open the hearts of all; for the moral influence of medicine is bound up with the treasures of life and health, and with all those endearing ties that make these treasures doubly precious. Nay, how often, with the hopes, or fears, of a blessed or an awful eternity!

Do not think me too enthusiastic, nor over-rating the profession you have chosen. Morally and intellectually I cannot over-rate it: and now, at the commencement of a new epoch of your studies, when toil and exertion are required, I would cheer and encourage you, by reminding and convincing you of the intrinsic gratification which these studies may afford, and of the nobleness of the objects for which they prepare you.

It is the fashion to decry our profession—to call it a poor profession; a degraded profession. If it be poor and degraded, is that the fault of the calling, or of those who practise it; or rather of those who should have governed and protected it? Is the art of healing in itself less noble, because its practitioners, unsupported by the arm of civil power, and too often unsustained by a consciousness of their own dignity, have not raised it to the place in society which it ought to hold? Poor it may be, but degraded it cannot, shall not be, so long as its foundation is science, and its end the good of mankind.

INSANITY IN WALES.

To the Editor of the Times.

SIR,—Your pages are so constantly open to the exposure of errors and to the advocacy of the cause of sufferers, that I feel assured you will give a place to the facts herein stated; and I beg you to use them as you think best.

During a recent visit to the northern counties of Wales I sought information on the state of the insane poor—it being a subject in which I have many years interested myself. I found in the counties of Anglesea, Carnarvon, Denbigh, Flint, Merioneth, and Montgomery, containing a population of 396,254 souls (195,721 males, 200,533 females), that there were 644 (306 males, 338 females) insane persons chargeable to the different parishes within those counties as “lunatic paupers.” This number, when compared with the population, will give us about one pauper lunatic to every 596 of the whole population—about one male in 639, and one female in 560. The number of the insane amongst the other classes could not be ascertained; but, from the many I was informed of, I am led to believe that in numerical proportion they are at least equal to their poorer brethren; making a frightful exhibition of the demented amongst our Welch neighbours.

The actual numbers of the insane poor in the different counties were said to be as follows:—

	Population.	In round Nos.
Anglesea . .	50,890	92 or 1 in 553
Carnarvon . .	81,068	146 „ 555
Denbigh . .	89,291	105 „ 850
Flint . .	66,547	62 „ 1,073
Merioneth . .	39,238	101 „ 388
Montgomery	69,220	158 „ 438
		664

These poor creatures were distributed and disposed of in the following manner:—

Mal. Fem. Tot.

6 13 19 in English lunatic asylums.
 17 15 32 in Welch Union Workhouses.
 140 163 303 living with relatives.
 143 167 300 living with strangers, or more properly “farmed out” to
 306 358 664 these, at various weekly sums, according to the degree of utility they could be of to their respective masters.

The few who were living in lunatic asylums cost their parishes, on an average, about 12s. per week; those in the Workhouses about 2s. 3d.; those with the relatives about 2s. 6d.; those with strangers about 3s. 2½d. The highest sum allowed to a relative was 5s. 6d.; to a stranger, 7s. per week. Several were stated to be provided for upon the handsome allowance of 9d. per week; whilst a few enjoyed riches with the more peculiar sum of 3d. per week.

A return which is now being made to the Poor Law Commissioners will hereafter give the facts connected with this subject, not only for the counties I have enumerated, but for the whole of England and Wales, in a fuller and more detailed form.

It will be anticipated that, with 664 insane people thus disposed of, there should

be in circulation abundance of reports and heart-rending narratives. Many of the poor lunatics would, unavoidably, be under severe restrictions. Some would be deemed unsafe to the public and themselves unless securely chained to the wall or the floor of their contracted apartments. Some would be thought well enough treated if confined to a chamber, and their food and their clothing supplied to them through some narrow opening; others would enjoy the outhouse and the society of the lower animals. Light clothing and spare diet would of course be prescribed in all cases as proper to bring down the high state of mania, and those who were melancholic and depressed would be happy indeed if left to their own wretchedness, and not roused up to shake off their lethargy and low spirits. Some are said to enjoy their freedom, and to roam uncontrolled about the country*, and such must occur where so many are so totally unprotected.

This leads to a most curious fact in Welch economy. I was assured, again and again, that there was not in the whole principality a lunatic asylum, either public or private, charitable or speculative. In vain I sought one†, and to this fact is to be ascribed that so few of the cases are placed in an asylum at all. Perhaps the greater mercy to the individuals themselves would have consisted in their total exemption from this, and in their remaining amongst their kindred or their countrymen.

So few of the lower class of the Welch, except some in towns or in the precincts of the inns, speak English, and this only for the purposes of commerce, or to qualify themselves for the duties of menial servants, and not to an extent which would enable them to comprehend anything higher,—whilst both the officers and servants of our English asylums, and the English public too, are equally ignorant of the Welch language,—that when the poor Welchman is sent to an English asylum he is submitted to the most refined of modern cruelties, by being doomed to an imprisonment amongst strange people, and an association with his fellow-men, whom he is prohibited from holding communion with. Nothing can exceed his misery: himself unable to communicate, or to receive communication; harassed by wants he cannot make known, and appealed to by sounds he cannot comprehend, he be-

* See a letter in the *Lancet* for June 25, 1842, in which gross enormities of this kind are described as occurring in the neighbourhood of Carmarthen.

† Since the above was written, Dr. Prichard, of Bristol, one of the Metropolitan Commissioners on Lunacy, has informed me, that there is a lunatic asylum near Haverfordwest, which he had visited. It is quite unknown in North Wales and elsewhere.

comes irritable and irritated; and it is proverbial in our English asylums that the "Welchman is the most turbulent patient wherever he happens to become an inmate." In vain is it in these cases that the professional treatment is judicious—the mortal humane—that the attendants are kind, or locality cheering; suspicious from the nature of his disease, and unconscious of the directions given him, he finds himself required to conform to the regulations of the establishment, which differ from his previous habits, and to submit to discipline for his own benefit, and he assumes all this to be so much insult and unkindness shown to him personally; and as he is not susceptible of an explanation to the contrary, he resents them with violence, and opposes them on the principle of self-defence. Then, again, as he cannot be approached by conversation, he loses those great advantages which in well regulated asylums are carried to a great extent, of personal communion with educated minds, who lead, direct, and control the wandering spirit of the lunatic, and bring it back by insensible degrees to his own guidance: he loses, indeed, all the advantages of the greatest of modern improvements in the treatment of the insane—judicious conversation with properly selected persons. It will not then be matter of surprise if the poor Welchman, after having undergone this species of solitary confinement in our English asylums, should leave it at least no better, and often worse, than when he entered it; and this, I believe, is usually the case.

I have known an instance of an individual becoming master of himself on quitting the control of those whose language he could not comprehend, and who previously was most violent and dangerous, and many instances could be cited of tranquillity occurring on hearing the sound of his native tongue. The effect of his own language upon the Welch lunatic I had lately an opportunity of observing in two cases, neither of whom spoke or understood English, and who derived more comfort and made more progress towards recovery through an occasional conversation with a Welch clergyman, who conveyed to them what were my wishes towards them, than by all the other means which are placed at my command.

In much the same situation as the pauper is the Welchman in the middle class of life—who, like the former, rarely speaks or understands English, and who, if insanity overtakes him, must be banished for security-sake amongst foreigners, or be maltreated by his well-disposed friends at home.

It is impossible this state of things can be known: or, if known, in fact, be estimated by its consequences; it could not if once appreciated remain as a blot upon Welch humanity and as a discredit to a country

renowned throughout the world for its practical benevolence. To give it publicity I have presumed to state it.

An attempt, I have the gratification to state, is making in the county of Denbigh to establish an asylum either to be maintained by the county or adjoining counties under the 9th George IV., or to be built by voluntary contributions, and to be conducted upon the self-supporting principle. Either form of such asylum would be the greatest blessing to the Welch lunatic, who, if then separated from his kindred and deprived for a time of his liberty, would yet receive advice and consolation in his native tongue; would be enabled to hold communion with his fellow-men; and would enjoy that privilege with which man alone is endowed—the gift of speech and the delights of conversation.

Towards such an asylum many donations are proffered, amongst them a munificent one in a piece of land of about 20 acres, most beautifully situated for the site of an asylum, and which cost its liberal donor about £2,000. With such a beginning the establishment must succeed, and to all others who have means, and to every Welchman, according to his means, I would presume to say "Go thou and do likewise."

Feeling assured that the nature of my subject will be in itself an apology for my intrusion upon the public and yourself,

I beg to remain, Sir, your obedient servant,

SAMUEL HITCH, M.D.

Resident Physician of the Lunatic Asylum
for the County of Gloucester.

Gloicester, Sept. 15, 1842.

LECTURES

ON THE

THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE II.

*Of the Bones, Articulations, Dimensions,
and Diseases, of the Female Pelvis.*

IT is necessary to commence with the anatomy and pathology of the female pelvis, as the process of delivery cannot be understood, nor any of the operations of midwifery, as craniotomy, induction of premature labour, and turning, performed; the forceps applied, or the placenta extracted, without a knowledge of the pelvis, both in its healthy and morbid states.

The *pelvis* consists of the *ossa innominata*, the sacrum, and the coccyx. The sacrum and coccyx form the back part of the pelvis, the *ossa innominata* its sides and front.

The *sacrum* is of a triangular shape, smooth, and concave on the anterior surface, and convex and irregular behind. Its base or superior surface is about four inches in breadth, and the central part, which is of an oval form, corresponds with the inferior surface of the body of the last lumbar vertebra, to which it is united by an elastic fibro-cartilaginous substance. The anterior part of this substance is thicker than the posterior, so that these bones form a considerable angle anteriorly, which is called the promontory, or great angle of the sacrum. From this on each side the bone expands, and is inclined outwards to the sacro-iliac symphysis. The superior lateral surface is broad and irregular, to articulate with the ilia, and in the recent state is covered with cartilage. The

inferior border is thin, and gives attachment to the sacro-sciatic ligaments. The anterior surface of the bone, which is broad at the upper part, and narrow towards the apex, presents four transverse ridges, formed by the ossification of the cartilages which separated the bones of the fœtus. At the ends of these ridges there are four pair of large foramina for the passage of the anterior sacral nerves. Both these sets of foramina communicate with the sacral canal, which is curved like the bone, and is of a triangular form. On the median line, behind the canal, is situated an irregular ridge, formed by the union of four small eminences, which correspond with the spinous processes of the four constituent vertebræ. At the base of the bone there are also two regularly formed oblique processes, to articulate with those of the last lumbar vertebra.

To the apex or inferior extremity of the sacrum is attached the *os coccygis*, which is of a pyramidal form, and in children consists of three or four small spongy bones, the bodies of as many rudimentary vertebræ, the uppermost of which is the largest, and has two cornua or eminences which project posteriorly. The coccyx is flexible, and also moveable backwards upon the sacrum, with which it forms an obtuse angle. There is a thin layer of fibro-cartilage between the contiguous ends of these bones; and this articulation is surrounded with a capsular ligament. An anterior ligament is placed along the front of the sacrum and coccyx, and a posterior ligament behind.

Each *os innominatum*, in young subjects, is divided into three separate bones: the ilium, the os pubis, and the ischium. The *ilium*, which forms the upper and largest part of the bone, is flat, broad, and somewhat triangular in its shape. Its outer surface is convex before and concave posteriorly. The inner surface of the bone, named the internal iliac fossa, is smooth and concave, at the under part of which is the linea innominata, forming the lateral part of the brim

of the pelvis. The superior convex border of the ilium forms the crest or spine, which terminates before, in the anterior and superior spinous process. A little below this is situated the anterior and inferior spinous process. The spine of the ilium terminates behind, in the two corresponding posterior spinous processes, below the latter of which is the sacro-sciatic notch. The inferior and outer part of the bone forms the upper and back part of the acetabulum.

The *ossa pubis* are situated at the inner and anterior part of the *ossa innominata*. The body of each os pubis is placed transversely before the anterior part of the ilium. The upper and inner part of the bone enlarges, and forms the crest or angle, from the outer and fore part of which the spine extends horizontally backwards, to form, with a similar corresponding ridge in the ilium, the *linea-ileo-pectinea*. The inner part of the os pubis becomes narrower, and runs downwards to join the ramus of the ischium, and form along with it one side of the arch of the pubes.

The *ischium* forms the inferior portion of the os innominatum and of the acetabulum. The body of the bone sends off the spinous process, which is about half an inch in length, and projects obliquely downward and backward, and gives origin to the innermost sacro-sciatic ligament. The lowest portion of the ischium, which is thick and narrow, terminates in the tuberosity, from which, on the inside, the smooth plane proceeds obliquely upward. In the natural situation of the *ossa ischia* their planes converge to the tuberosities, and this has an influence on the foetal head in labour as it approaches the outlet of the pelvis.

The obturator, or thyroid foramen, in the anterior part of the pelvis, is formed by the ischium and os pubis.

Articulations of the pelvis.—The bones of the pelvis are united by cartilages and ligaments, and never separate during labour, or at any other time, so long as they continue in a healthy state. The surface of each os pubis is covered at the symphysis with a layer of cartilage, and between these two layers of cartilage an elastic fibrous tissue is interposed, which prevents their separation from one another: the fibres of this substance pass between them transversely. I have only once seen a small cavity between the cartilages covering the bones of the pubes. A strong ligament is stretched across under the symphysis, and the whole articulation is surrounded with ligamentous fibres. The articulating surfaces of the *ossa innominata* and sacrum are covered with cartilage, and have corresponding elevations and depressions. Each sacro-iliac symphysis is surrounded by strong ligamentous bands, and the sacro-sciatic ligaments assist in pre-

venting a separation of the bones. These ligaments extend from the sacrum and coccyx to the spinous process and tuberosity of the ischium, by which means the sacro-sciatic notch is converted into an oval foramen, through the upper and back part of which the sciatic nerve passes to the lower extremity.

The pelvis is divided into the brim, the cavity, and the outlet.

The *brim*, or superior aperture, is usually of an oval form, to correspond with the shape of the foetal head. The distance between the base of the sacrum and symphysis pubis is usually about four inches. This is called the conjugate or sacro-pubic, or antero-posterior diameter of the brim. The long or transverse diameter, which crosses this at right angles, extends from ilium to ilium, and usually measures about five inches. The plane of the brim is inclined downward and forward, so as to form a great angle with the spinal column.

The *outlet* of the pelvis is of an irregular quadrangular form, and is not parallel with the brim. A line drawn from the inferior border of the symphysis pubis to the extremity of the coccyx, when the bone is pressed back, measures five inches. This is the longest diameter of the outlet, and it crosses at right angles the long diameter of the brim. Between the tuberosities of the ischia the distance is about four inches.

Behind the symphysis pubis the *cavity* of the pelvis is an inch and a half in depth; it is three inches deep on the sides, and about six from the base of the sacrum to the point of the coccyx. A line drawn through the brim, cavity, and outlet of the pelvis, equally distant at all points from its sides, represents the *axis* of the pelvis. In the living body it is impossible to determine precisely the course of this line, and it is sufficient, in practice, to know that the pelvis is a curved canal, and that whatever passes through it must follow a line corresponding with the curvature of the sacrum. The head of the foetus is of an oval shape, and it usually measures four inches from the forehead to the occiput, and three between the parietal protuberances. In natural labour the head enters the brim in such a manner that its diameters nearly correspond with those of the pelvis, the ears being near the sacrum and pubes, and the forehead and occiput placed towards the sides of the pelvis. As it descends through the cavity to the outlet, the opposite sides of the head are pressed against the converging planes of the ischia, and the occiput is turned so as to present under the arch of the pubes, and the forehead to press against the perineum and coccyx.

There are various soft parts which connect the uterine organs, bladder, and rectum, with the bones of the pelvis, and diminish their irregularities. The outlet is nearly closed

by a septum formed of parts which are chiefly muscular: the levator ani and coceygæi muscles form the superior, and the sphincter ani, transversus perinæi, and constrictor vaginæ, the inferior plane of muscles. The hemorrhoidal and pudic vessels and nerves, with adipose and cellular membrane, also contribute to fill up the inferior aperture of the pelvis. This septum at the outlet of the pelvis is pierced by the urethra, vagina, and rectum, in the mesial plane. An aponeurosis arising from the great sciatic ligament and the inner edge of the arch of the pubes covers the inferior surface of this septum. In the living body the psœ muscles, with the iliac blood-vessels, extend along the sides of the brim of the pelvis, and modify its form.

In infancy the pelvis is long and narrow, the sacrum is slightly curved, and the transverse diameter of the brim is shorter than the sacro-pubic. The form of the brim and outlet of the foetal pelvis is preserved through the whole course of life in the male. The bones of the male pelvis are stronger and thicker than in the female, the cavity is less capacious, and the pubic arch is smaller.

Diseases of the articulations and bones of the pelvis.—The cartilages interposed between the ossa pubis and the sacrum and ilia, may become softened, or be destroyed by inflammation and ulceration, like fibro-cartilage in other parts of the body, and the bones may separate and become moveable on each other. This rarely happens, except in pregnant or puerperal women; and is most frequently one of the remote consequences of inflammation of the veins, absorbents, or muscular coat of the uterus.

Arrest of development.—In some women the pelvis is not developed in the usual manner, and it remains small through life, though not distorted. Its condition is very different from what it is in childhood. When this arrest of development takes place in the pelvis, even though the foetal head should not be remarkably large, all the evil consequences which usually result from a disproportion between the head and pelvis follow. Mr. Shaw attributes this interrupted growth and defective capacity of the pelvis to rickets; but in the person from whom this striking specimen [here Dr. Lee showed a preparation] of the disease was obtained, there was no bending of the spine or cylindrical bones of the extremities, or any appearance of rickets in any part of the body. The brim of the pelvis is of an oval form, and measures three inches from the promontory of the sacrum to the symphysis pubis, and four inches and a half in the transverse diameter. The distance between the tuberosities of the ischia is three inches and a quarter. The ossification of the sacrum and ossa innominata is very imperfect. The

bones of the extremities were not bent, and there was not the slightest external appearance from which the actual condition of the pelvis could have been known before the labour commenced. It took place on the 22d of April, 1836, and the nates presented and were extracted by a blunt hook passed over one of the groins, when they could not pass by the natural efforts. The trunk and upper extremities of the fœtus were drawn through the pelvis without much difficulty, but the head remained long immovably fixed above the brim: the perforator was passed up to the occiput, and the head opened and ~~extracted~~ with the crotchet; but she died from inflammation of the uterine organs and cellular membrane of the pelvis. Had the state of the pelvis been known, premature labour should have been induced.

Distortion of the pelvis from malacostœon or mollities ossium.—When the bones of the pelvis are affected with this disease, they become so soft that they cannot support the weight of the head, trunk, and upper extremities. The quantity of earthy matter in them is much diminished, and their internal structure is often completely changed. Within a thin bony layer on their surface there is sometimes contained a soft bloody substance of a dark colour. This disease occurs only in adults, and may be confined to the bones of the pelvis, or it may affect at the same time the vertebral column and the long bones both of the upper and lower extremities. In some cases the bones of the extremities have been fractured by the application of a slight external force, or by the action of the muscles in turning the body round; and as the disease proceeds, the bones of the spine and extremities have become bent, and an extraordinary degree of deformity and shortening has taken place. In one case the trunk of the body, at the time of death, measured only thirty-two inches in length; and in another case, related in Gooch's Surgical Observations, the patient was found to have lost two feet two inches of her natural stature. The brim, cavity, and outlet of the pelvis, are all more or less changed by this disease. The promontory of the sacrum projects unusually forward, and encroaches upon the short diameter of the brim. In some cases the symphysis pubis and great angle of the sacrum have been forced within an inch of one another. Sometimes the base of the sacrum is pressed down by the weight above into the cavity of the pelvis, and the last lumbar vertebra comes to occupy its place. The lower end of the sacrum is often also bent upward, and the long diameter of the outlet proportionally diminished. The heads of the thigh bones press the sides and front of the pelvis inward and backward, towards the sacrum, so that the oval shape of the brim becomes triangular

or cordiform. The tuberosities of the ischia are sometimes pressed together, so as to be almost in contact, and the arch of the pubes so contracted that it cannot be said to exist.

When this affection has commenced in the bones of the pelvis, it proceeds with greater or less rapidity till the high degree of distortion is produced which you see in this pelvis, [here a preparation was exhibited] and in some of these casts, taken from the pelvis of women who became pregnant, went to the full period, and died after they were delivered by the Cæsarean operation. The disease runs its course with great celerity in some cases; in others the softening of the bones goes on for several years. This happened in the instance related by Sir Charles Bell, where the Cæsarean section was performed, the patient having been repeatedly pregnant, and as the disease advanced greater and greater difficulty was experienced in effecting the delivery in each successive labour, until, at last, the dimensions of the brim of the pelvis were so diminished that it was found impossible to deliver the child by craniotomy. The distance from the sacrum to the symphysis pubis did not exceed an inch, and there was not sufficient space on either side of the pelvis to admit of the head being drawn through by embryotomy, even if it could have been performed.

This fatal disease is very rarely met with in London. Only one case has come under my observation, and from its history, perhaps you will learn, better than from a general description of the disease, its early symptoms, and the changes which take place in the pelvis during its progress, and the great and almost insurmountable difficulties it presents to delivery if the pregnancy is allowed to go on to the end of the ninth month. A woman, aged 30, had been forty-eight hours in labour, with her fourth child, when I was called to deliver her, on the 17th of January, 1830. The pelvis was very greatly distorted, the whole head of the child was above the brim, and the orifice of the uterus was not more than half dilated. The pains had nearly ceased, and she was completely exhausted. After perforating the head, three hours elapsed before I succeeded in extracting it with the crotchet, and not till all the bones had been literally torn to pieces. She recovered as if it had been a natural labour. She was a native of Manchester, and had spent several years in one of the cotton manufactories of that town. She married at 20, and had given birth to three children at the full period without assistance. During the fourth pregnancy, she suffered much from pains about the sacrum and ilia, which were supposed to be rheumatic, and she had become unable to walk. On the 11th July, 1832, this patient was again in labour at the

full period, having refused to submit to the induction of premature labour. The labour continued upwards of thirty hours before the os uteri could be felt, or the presenting part ascertained; and during fifteen hours it appeared extremely probable she would die undelivered if we did not perform the Cæsarean operation. The head was perforated and extracted, but with still greater difficulty than in her previous labour. She recovered again, in spite of all the violence that had been employed in extracting the head, as if it had been an easy and natural labour.

In the month of June 1833, when she was at the end of the third month of her next pregnancy, I passed up this slender silver catheter [showing the instrument] into the uterus, and drew off the liquor amnii, and the foetus was expelled eight days after without any assistance, and she recovered as if it had been a common abortion. On the 12th February, 1835, I induced premature labour in the same patient at the commencement of the seventh month of the following pregnancy, and the foetus was expelled without assistance, dead, and she recovered again in the most favourable manner.

On the 19th of January, 1836, when she was at the end of the sixth month of pregnancy, I made an unsuccessful attempt to perforate the membranes; the ergot of rye was given, but it completely failed to excite uterine contractions. Other attempts were made to bring on labour during the two succeeding months, without effect, and it is probable she would have gone to the full period had I not, in the meantime, provided myself with this stiletted probe-pointed silver catheter [showing the instrument]. This was readily passed into the uterus, and the membranes perforated on the 14th March. Labour followed in a few days, and the nates presented. When the os uteri was sufficiently dilated, the point of the crotchet was forced through the anus into the pelvis of the foetus, and fixed upon the bones, and the trunk and extremities of the child were drawn with great difficulty through the mother's pelvis. The perforator was then passed up to the occiput, and a free opening made in the back part of the skull, and the head extracted with the crotchet. Several hours were spent in accomplishing the delivery, and she died the following day, with vomiting and other symptoms of ruptured uterus. On dissection, I found the muscular coat of the anterior part of the neck of the uterus deeply lacerated; the brim and cavity of the pelvis, you see, [showing the preparation] are very much distorted. The last lumbar vertebra occupies the usual situation of the base of the sacrum, which is pressed down into the cavity of the pelvis; the bones of the pubes

have been forced together, so that the brim has a triangular shape. On the left side, a line drawn from the middle of the last lumbar vertebra to the ilium behind the acetabulum measures one inch and a half. On the right side, a corresponding line measures only an inch and a quarter. From the middle of the last lumbar vertebra to the bones of the pubes, the distance is an inch and three quarters. At the outlet the tuberosities are only three or four lines asunder, and there is no pubic arch. The lower extremity of the sacrum and coccyx pass horizontally forward, so that the apex of the coccyx is only two inches and a quarter from the point where the tuberosities of the ischia nearly meet; the bones of the extremities were not affected.

As pregnancy and delivery generally accelerate the progress of mollities ossium, I now think it would have been better practice, in this case, to have interrupted the pregnancy, or induced abortion in the course of the second month, which could safely have been done with this probe-pointed instrument, had I possessed it at the time.

Where the pelvis has been fractured, or the brim, cavity, or outlet, is much obstructed by exostoses, it would also be proper to induce labour at an early period of pregnancy, which would render the Cæsarean operation unnecessary.

In some systems of midwifery, instruments have been described for measuring the dimensions of the pelvis in the living body, and representations given of pelvimeters, some of which are intended to be applied, like a pair of compasses, to the outside of the pelvis, and others to be passed within it. If you examine this pelvis distorted by malacosteon, you will at once see that these instruments can be of no use whatever in practice: the bones of the pubes are here pressed together, so that the points of a pelvineter, applied over the symphysis pubis and base of the sacrum, would indicate a space in the short diameter of the brim of the pelvis about two inches greater than actually exists.

All the morbid conditions of the pelvis can be ascertained with sufficient precision during life by introducing the fore finger of the right hand into the vagina, and passing it around the interior of the pelvis. If the point of the finger cannot touch the promontory of the sacrum, there is little or no distortion of the brim, and by moving the finger from side to side and backward, it will readily be discovered if the tuberosities of the ischia are at the usual distance from each other, and if the direction of the sacrum and coccyx is altered.

Distortion of the pelvis from rickets.—The softening of the bones of the pelvis from rickets occurs generally before puberty,

and, in a great proportion of cases, the long bones of the extremities are likewise affected, and sometimes, also, the spine. But the spine is not unfrequently affected both with angular and lateral curvature, from ulceration of the vertebræ and cartilages, where the pelvis remains in the natural state. The changes produced in the pelvis by rickets are numerous, and do not differ essentially from those observed in malacosteon. In this short skeleton [showing a specimen] the head is remarkably large, the long bones of the extremities are all bent, and the pelvis is precisely in the same condition as the pelvis which you have just seen distorted by mollities ossium. The base of the sacrum is pressed forward, and the front and sides of the pelvis inward and backward, so as to give the brim a triangular shape. The tuberosities of the ischia have likewise been pressed into contact, and the arch of the pubes destroyed.

There is another form of distortion of the pelvis from rickets seen in other pelves and casts upon the table. The brim in these is of an elliptical shape, and the tuberosities of the ischia, instead of being nearer one another than usual, are separated to a greater distance, and the outlet of the pelvis appears enlarged. The sacrum, in most of these, is nearly straight from the base to the apex. In several, the distortion is greater on one side than the other. In all, the distortion has reached a certain point, and then appears to have ceased to increase, unlike what happens when the pelvis is affected with malacosteon.

The regular process of delivery is necessarily interrupted by all these morbid states of the pelvis. When the distortion of the brim is slight, the head is usually forced through after a protracted labour, and the child is often injured from the pressure it has sustained. When the distortion is greater, the head becomes arrested in the brim, and cannot pass till its volume is reduced: and where the distortion is in a still higher degree, the head of the child never enters the brim, however long the labour may be allowed to continue.

If the bones of the extremities are not much bent, and the pelvis not highly distorted, we are seldom consulted until the full period of pregnancy has been reached, and the person has been long in labour. The delivery may require to be completed with the perforator and crochet, and the dimensions of the pelvis are then, for the first time, ascertained. In a subsequent pregnancy, it becomes necessary to induce premature labour at the end of the seventh or seventh and a half month—an operation attended with little danger to the mother, and which has preserved the lives of many children which would otherwise have been

sacrificed. Even in a first pregnancy, when it is known that the pelvis is very much distorted, I hold it justifiable to induce premature labour.

RESEARCHES
ON THE
PATHOLOGY, PHYSICAL SIGNS,
AND DIAGNOSIS,
OF
DISEASES OF THE HEART AND
ARTERIES,
IN CONNECTION WITH
THE SOUNDS OF THIS ORGAN.

BY T. H. MOORE, A.B. M.B. T.C.D. &c.

[Concluded from p. 16.]

THE accession and progress of the symptoms, the physical signs furnished by auscultation, and the pathological lesions ascertained in the post-mortem examination, institute a degree of relationship between the preceding case and one published in the *MEDICAL GAZETTE* for June 25, 1841. In adopting some arrangement in our inquiries, it may possibly be attended with beneficial results to investigate—

First: the primary causes which predisposed to the formation of an aneurismal diathesis in the circulatory system of this patient, and of the morbid alterations in the viscera of the thoracic and abdominal cavities.

Second: how far we are justified in asserting that this aneurismal diathesis is capable of being diagnosed; that its recognition is dependent upon and characterized by a certain train of symptoms and physical signs.

Third: to what extent we are warranted in deciding upon the much-controverted question of the muscularity of the middle coat of arteries, referring to the pathological appearances recorded in the preceding case, and those observed in others, in many respects similar, as the basis of our judgment.

In the history obtained on the patient's admission into hospital, and from the symptoms by which the disease was ushered in, we possess sufficient evidence to prove that the primary predisposing causes of the aneurismal disease, in one division of the circulatory system, did originate in an acute inflammatory attack of the serous and muscular structures of the heart at a

period antecedent even to that stated, idiopathic in its character, not consecutive to any form of specific inflammation prevalent in the system, but probably co-existent with inflammation of the serous membrane of the lungs, or abdominal viscera, which inflammation, unchecked by the treatment pursued, progressed gradually, and finally assumed the subacute character so evident in several parts of the system.

In no part of the animal economy are the effects of inflammation, varied though they be in their forms, more manifest than in the structures of the heart, since, in the ventricular and auricular parietes of this organ, we may meet with the intermediate and extreme degrees of hypertrophy and atrophy; of induration and softening of all the tissues, and not unfrequently in the muscular parietes of the same cavity there are presented to our view pathological alterations diametrically opposed. In the left ventricle of this heart an opportunity has been afforded us of observing the change of colour; the flabbiness; the loss of tone; the partial degeneration of the muscular structure; morbid lesions consequent upon a subacute inflammatory action, constituting the rudimentary stage, and being introductory to the formation of an incipient aneurism; in which circumscribed space, a small sacculated pouch, composed of the serous and muscular structures of the ventricle, must have resulted, from the enfeebled, attenuated, relaxed condition of the fibres; from their inability to contract energetically in unison with those in the vicinity assisting in the propulsion of the arterial column of blood, and from the inadequate resistance opposed by them to the volume of the circulating fluid during the systolic action of the heart.

To the same source we may trace the predisposing causes of the lesions in the arterial tunics. To such we cannot deny a susceptibility to be attacked by the acute, subacute, and chronic stages of inflammation: nor can we exempt the serous, the fibrous, and other coats of these vessels, from the pathological alterations, so manifest in other portions of the system, consequent upon this inflammatory action, whether of a healthy or unhealthy — traumatic or atraumatic — character.

It now devolves upon the writer to advert to the much-controverted question of the muscularity of arteries—a subject of the highest importance—one which requires to be approached with caution, and treated of in a circumspect manner, when involved therein there are the opinions of the most eminent British and continental anatomists, physiologists, and pathologists; inasmuch as this question—so long at issue, but now apparently settled by the positive assertions of some, and the passive acquiescence of others—must be grappled with anew. Previous to expressing any opinion on this subject, I propose to extract, for the perusal and information of the reader, such portions of the writings of others as have direct reference to the subject.

“But it is the coat, which is placed between these two, that properly forms the arteries. It is dense, close, thick in proportion to the calibre of the trunks; yellowish; sometimes greyish; composed of very distinct fibres, adhering to each other, easily separable, however; disposed in concentric layers, nearly circular, and intimately united externally to the cellular coat, but not so much so to the internal membrane. None of these fibres follow a longitudinal direction. They do not at all appear to be muscular, but form what is called the elastic tissue.”—*Knox's Translation of Cloquet's Anatomy*, page 646.

The fibres of the elastic coat of arteries are distinguished from muscular fibres by chemical characters, as Berzelius has pointed out. The muscular substance is soft, and lax, and contains more than three-fourths of its weight of water, while the arterial fibre is dry, and very elastic. Muscular substance has the same chemical properties as fibrin of the blood; is soluble in acetic acid, with difficulty soluble in mineral acids, with which it forms compounds difficult of solution; while the arterial fibre is insoluble in acetic acid, but readily soluble in mineral acids, and its solution is precipitated neither by alkali nor ferro-cyanuret of potassium, which must happen if it contained fibrin. Dr. Hodgkin has also observed, that the fibres of the middle coat of arteries, when examined by the microscope, do not present the transverse striae which are seen on muscular fibres, &c. The dif-

ferent arguments for the existence of the pretended muscular contractility of arteries, which have been adduced from comparative and pathological anatomy, are of no weight. Not merely, however, are the arguments for the muscularity of arteries without grounds, but there are also counter arguments to disprove their muscularity. Berzelius justly remarks, that the strongest galvanic and electric stimuli, which produce contractions in all true muscular structures, excite not the smallest motion in arteries. Nysten repeatedly instituted galvanic experiments on the aorta of criminals just beheaded, but did not perceive the slightest contraction; nor could he excite any contractions in the aorta abdominalis of fishes by means of galvanism. Bichat and Wedemeyer performed similar experiments with the same results. I have myself made frequent experiments, with the aid of galvanism, to determine this question; and neither in frogs, with feeble or powerful degrees of galvanic influence, nor in mammalia—for instance, rabbits—with a pile of from sixty to eighty pairs of plates, have I been able to produce the slightest trace of contraction of the arteries.”—*Müller's Physiology*, translated by Baly, p. 202-3-5.

“Hypertrophy is another alteration to which the middle coat is often liable: when in this state, its natural organization becomes much more apparent: the yellow fibrous tissue of which it is composed becomes as evident in the human subject as it is in the horse; but never does it present any trace of muscular fibre, even in the most extreme cases of hypertrophy.”—*Andral's Pathological Anatomy*, translated by Townsend and West, p. 374, vol. ii.

John Hunter has expressed himself in a decided manner on this subject: his opinion is comprised in the following:—

“Every part of the vascular system is not equally endowed with muscles: the larger vessels, especially the arteries, being chiefly composed of elastic substances, whilst many parts of the smaller, or what are called the capillary vessels, appear to be entirely muscular.”

From a careful examination of the arterial tunics in this specimen, and other preparations similarly diseased, I feel a degree of confidence in protesting against their assertions, and advocating

in unequivocal terms that the fibres of the middle coat of the large and small sized arteries, be their calibre what it may, are essentially muscular; that they possess the appearance, the arrangement, the physical and chemical properties, and are subject to the same pathological lesions, as the muscular fibres in the tubular apparatus of the lungs, and the fibres in the different divisions of the alimentary canal; all which properties, however equivocal anatomists, physiologists, and chemists, may pronounce them to be in the healthy condition of the artery, yet are rendered so manifest in the pathological lesions to which these vessels are subject, that they are more than sufficient to dissipate our doubts, and confirm these statements. Who, in the current year, would have the hardihood to assert that the bronchial tubes of the ternary, quaternary, or septenary order of bifurcation, were destitute of muscular fibres; because to the eye of the anatomist they are often invisible; by the hand of the anatomist they frequently cannot be traced; and in the analytical experiments of the chemist, they may be found deficient in that proportionate quantity of fibrine entitling them to rank as muscular? Who is that physiologist, be his experiments performed with the most exquisite dexterity, who has succeeded in producing contractions of the muscular fibres in the bronchial tubes by the electric and galvanic stimuli, even though he employ triple the number of plates with which he failed when experimenting on the middle coat of the arterial tubes?

Far be it from me to speak disparagingly of those men who have shed such lustre in the several departments of science to which they have devoted their energies: far be it from me to deprecate, in the slightest degree, the accuracy of their experiments and the correctness of their observations; but in asserting that the fibres of the middle coat of arteries are as essentially muscular as those of the bronchial tubes and the alimentary canal, this opposition to their opinions, and advocacy for the muscularity of arteries, are in strict conformity with the results of pathological anatomy, exhibiting in many morbid preparations their direction, their arrangement, so remarkably developed, so clearly demonstrated, that our acquiescence in the reality of their existence is in-

stantly ceded, however reluctantly it may have been granted.

Furthermore, were but a few of the many specimens of thoracic, abdominal, and other aneurisms, or of diseased arteries, carefully preserved in our metropolitan museums, dissected with an ordinary degree of skill, the writer ventures to affirm that it is more than probable the fibres of the middle coat have become so much hypertrophied, so remarkably developed, that they can be obviously and convincingly demonstrated to be as essentially muscular as the fibres of the bronchial tubes in chronic bronchitis with dilatation of the bronchi, and those of the alimentary canal in the immediate vicinity of a contraction of its calibre.

In a variety of pathological lesions of the arterial system, the preparations of which were subjected to microscopic examination, the formation of small circumscribed accumulations of yellowish-coloured particles has been noticed, varying considerably in size, from a pin's point to the circumference of a silver penny; and in consistence, from a state of perfect fluidity to that of thick cream, collected into a soft pulp or pap, which, when washed away, an eroded, irregular, jagged depression was distinctly apparent: the continuity of the fibres of the middle coat being intercepted, and, as it were, destroyed by ulceration. To such a degree had this destructive process progressed, that the external cellular tunic has been visible underneath, and when held to the light was perfectly diaphanous; whilst the internal lining serous membrane, covering these yellow-coloured patches, had lost much of its natural polish, was discoloured, hypertrophied, rugous on its surface, in many places thrown into small but distinct folds, easily separable from the middle coat; but very seldom have I seen in this diseased condition of the artery an abrasion of its surface; whilst a complete dissection has been performed between it, and the middle coat, by the process of suppuration, which had originated in, was confined to, and progressed during the patient's life-time amongst the muscular fibres of the middle coat.

These observations, based upon the repeated dissections of morbid specimens of the arterial system made in the General Military Hospital, Phoenix Park, I am aware are at variance with

the experience of Professor Porter. His remarks on this subject are contained in the subjoined extract from the valuable work on Aneurism lately published :—

“The lining membrane, covering one of these spots, becomes soft, and soon exhibits a distinct ulcer, which proceeds from within, eroding the middle coat, either through the entire thickness to the cellular, which is then easily distended to the aneurismal sac, or so far that it shall be likely to give way, and tear under a trifling shock—even the impulse of the circulation.”—P. 43.

In the majority of cases the disease was pronounced to have originated in the middle coat, by the depositions of small globules of lymph in the substance of the coat, consequent upon the irritated and inflamed condition of its structures. These globules of lymph cohering to each other, formed small, circumscribed, concrete masses of fibrine, adhering to, and not unfrequently imbedded in, the substance of the middle coat: their organization at those parts was progressive; their increase of size, and transition from a semifluid, tenacious exudation to the firm, semitransparent, resisting force being commensurate therewith. In other parts there was a total arrest in the organization and further development of these deposits of coagulable lymph, from the non-establishment of a distinct and separate circulation of the vivifying fluid. The vitality of these fibrinous deposits being no longer maintained, the attraction of the lymph-globules for each other ceased; their cohesion could no longer be sustained: disruption of the concrete masses, and a final resolution into their primitive globules, ensued, which, from their change of colour, from their appearance, and from their chemical properties, have been termed pus-globules or purulent matter. From the combined action of these pus-globules, from the eroding, destructive influence they exercise upon the surrounding tissues, and, principally, from a deficiency in the vitality of the middle tunic itself, a disorganization of the individual coats of the vessel, such as has been described, progresses in some with extreme rapidity, in others with comparative slowness.

Having adverted to the first and

third division of our arrangement, it remains for us to glance at the second, and consider how far the aneurismal diathesis which prevailed in this patient was capable of being diagnosed. I must premise that the data upon which the diagnosis of every case of thoracic aneurism ought to be based, should be derived from the symptoms and physical signs furnished by the organs of circulation, those by the venous and arterial systems in particular; from the symptoms and physical signs furnished by the organs of respiration; and lastly, from the symptoms, afforded by the glandular and nervous systems, in connection with the previous history.

In the case of true circumscribed consecutive aneurism of the ventricular parietes already recorded, we were prevented from asserting in positive terms the practicability of its being diagnosed, in consequence of its complication with a permanently patulous condition of the auriculo-ventricular apertures. In the present instance we labour under a similar disadvantage: the probable regurgitation of the arterial column of blood being chiefly instrumental in the production of the physical signs reported, more in consequence of the disproportion existing between the calibre of the artery and that of the ventriculo-aortic aperture, than from the disorganized state of the valvular structures, which were comparatively exempt from disease. To the observations appended to the former case no important addition can be made; for the particulars of which the reader is referred to the 40th number of the *MED. GAZETTE*, N. S. 1840-41.

The cavity of the face and upper extremities, which formed a prominent feature in this patient, seems attributable to a partial obstruction in the return of the column of venous blood: this obstruction may have been caused by the displaced and partially compressed lung, by the liquid effusion into the pleural cavity, but more especially by the dilatation of the ascending and transverse portions of the aorta: the extreme turgescence of the venous system, the consequent lividity of the face and superior extremities, their persistence and increase with the advance of the disease, have proved on many occasions most valuable auxiliaries in enabling the writer to suspect the in-

ipient and diagnose the more advanced stages of aortic aneurism. It is a matter of the highest importance that particular emphasis be laid on the signs furnished by the venous system, when we reflect upon the proximity existing between it and the arterial system, the almost certainty of its exhibiting at an early period of the disease those visible alterations, the effects of pressure, exercised by lesions in the coats of the arterial trunks.

To exemplify its importance, we need only refer to those pathological specimens of lesions of the arterial tube, in which adhesion has taken place between the cellular coats of these vessels; and observe the thickened, hypertrophied condition of the venous tunics, the exudation of plastic lymph on its internal surface of recent or chronic date, the partial or complete agglutination of the opposed sides, the perfect or imperfect obliteration of the venous trunk, or intersection of its cavity, from the formation of a fibrinous diaphragm, or transverse fibrous bands, dividing it into two or more distinct compartments, through which, as through constricted channels, the blood flows slowly, and with difficulty regains the right cavities of the heart: all these pathological changes may be traced to the irritation and inflammation excited in the vein from its connection with the aneurismal pouch, which, in the process of time, from its increase in size and attenuation of its parietes, may terminate by a sudden rent, and establish a free communication between these two vessels, and an intimate commingling of the advancing arterial and returning venous column of blood.

Next in importance may be mentioned the signs furnished by the organs of respiration and deglutition, as also the symptoms proceeding from pressure on the nervous system; and an overstretched condition of the minute terminating and anastomosing filaments of the cardiac and pulmonary nerves. In this patient's case, however, the thoracic complication rendered of less value those symptoms and signs, which, in others, have proved most valuable auxiliaries in enabling us to form a diagnosis.

From the extent of the cardiac dullness; the prolonged, laboured, and diffused impulses; the presence of a

thrilling, twanging vibration; the bounding, jerking, vibrating pulsations of the arteries, of large and small calibre; from the rushing, whizzing murmur, synchronous with the pulse, the ventricular contraction, and the propulsion of the column of blood into the vessels, constituting the arterial first sound; from the immediate replacement of this by a retroceding gentle-blowing murmur, rendering obscure the clear, sharp, well-defined clack, characteristic of the arterial second sound; from the persistence and regular succession of these auscultatory signs, in connection with the previous history and existing symptoms, it was conjectured that regurgitation of the arterial column of blood, after its propulsion, took place into the ventricle, through an aperture partially, but permanently patulous, not so much from disorganization of the valvular structures, as from a morbidly dilated and diseased condition of the coats of the ascending and transverse divisions of the arch.

In connection with the subject of aneurism, the following case may be adduced as illustrative of the symptoms and physical signs attendant upon the more advanced form of sacculated aneurism of the abdominal aorta.

CASE. — Aneurism of the abdominal aorta, terminating by a transverse fissure in the coats of the sac, and extravasation of blood between the layers of the transverse meso-colon—the pulsating abdominal tumor accompanied by a vibratory thrill, and intense whizzing murmur, &c.

Richard Sullivan, a private in the 10th Foot, 45 years of age, of strong muscular frame, admitted into the General Military Hospital, Phoenix Park, Feb. 28, 1842, with a violently pulsating tumor situated in the superior division of the abdominal cavity. The surface of the abdomen, when viewed horizontally, presents a prominent fullness, well defined, circumscribed in extent, and possessing a distinct throbbing, pulsating appearance: this fullness is dependent upon a large-sized globular tumor, occupying the space between the xiphoid cartilage and the umbilicus, and extending into the right and left hypochondriac regions, which, when grasped, is found to be slightly moveable, almost fixed, but expanding

equally, with extremely violent, energetic force, so that, at each impulse, the hands are repelled by an irresistible vigour, and carried beyond the limits of the epigastric and umbilical regions.

In this tumor are two distinct actions, the expansive, or diastolic; the contractile, or systolic; each accompanied by vigorous purring, thrilling vibrations, uniform in their intensity, regular in their succession, constant in their presence, but more prolonged as to duration in the former than in the latter. Over whatever part of the tumor the stethoscope is placed, the head of the auscultator is elevated with a degree of force quite disagreeable; directly upwards, if applied to its summit; outwards, and with an oscillatory motion, if applied to its sides; downwards, and with a marked degree of resiliency, if applied to its base. Each diastolic pulsation of this globular tumor is preceded and accompanied by an extremely loud and vigorous "thrumming buzz," or whizzing murmur; its duration coincides with the rush of blood through the abdominal aorta into the aneurismal sac, is synchronous with the first sound of the heart in the cardiac region, and pulse felt in the large arteries, but more prolonged than either. This, which may be denominated the first sound, is succeeded by another, dull, and undefined in character, which, though synchronous with the heart's second sound, possesses not the sharp, short, clacking character so peculiar to it. This buzzing murmur can be detected by the ear, without the aid of a stethoscope, and is present in the arterial divisions below the umbilicus, but comparatively feeble and indistinct. In the iliac and femoral arteries there exists no discrepancy in the strength of their pulsations; the normal sounds of the thoracic and abdominal aorta can be traced along the spine, stronger in the former than the latter, but free from the bellows murmur so distinct anteriorly; it cannot be pronounced to exist, even at the point where the aneurism is supposed to take its origin. Pressure on the 10th, 11th, and 12th dorsal vertebræ occasions severe pain; but no prominence of the spinal column is visible. The physical signs anteriorly undergo no alteration by this change of position. Heart's action strong, not violent; sounds preserve

that proportionate degree of clearness observable in health.

History.—His occupation as shoemaker in the regiment, and consequently the constant pressure applied to the epigastric region, are considered by him the chief causes in producing the present disease. In the month of November, he distinctly recollects being seized with a violent excruciating pain in the "pit of the stomach," whilst stooping over his work; and from this period he has been frequently troubled with cramps and colicky pains. At Christmas he obtained furlough to visit his friends in the south of Ireland, but was not at the time aware of a pulsating tumor in the abdomen. His attention was first directed to it six weeks since, from the constant throbbing pains, slight beatings, and flutterings, he experienced at the stomach. The increase in the size of the tumor has been extremely rapid within the last three weeks, and the amount of his sufferings proportionally augmented. The bowels have been constipated from the commencement; obstinately so of late, requiring injections and strong purgative medicines to evacuate them. The colicky pains and cramps, always worse during the constipated state of his bowels, are of that torturing nature, that during a paroxysm he writhes in the bed, and screams aloud. The sensation he experiences is, in his descriptive language, that of his bowels being coiled, twisted, knotted, and rolled together into a mass. These pains are felt in the loins, along the vertebral column, and every part of the abdomen. The pulse is full, and not accelerated; tongue moist; appetite good; no thirst.

On the 11th March he sat up in bed, gave a violent scream, exclaimed he was about to die, and in less than three minutes he expired. Some relief was afforded by the administration of injections and opiates since his admission.

Autopsy, twenty hours after death.—The surface of the body is blanched; countenance not distorted; muscles extremely rigid. The circumscribed prominent tumor described during life is no longer apparent. After throwing down the flap of abdominal muscles, a large dark-coloured coagulum was exposed, occupying two-thirds of the abdominal cavity, extending across the

epigastric and umbilical regions into the right and left lumbar. This coagulum was contained in a perfect serous envelope, so that on its anterior and posterior surfaces it presented the glistening polished appearance peculiar to serous membranes. In a more advanced stage of the dissection, it was discovered that the rent in the sac had occurred opposite to the division of the transverse meso-colon, into the superior or ascending, and inferior or descending, layers; the blood being poured into the cavity of this process of the peritoneum, escaped extravasation into the cellular tissue, and the consequent dissection of the several organs in the vicinity of the aneurism. In front of the aneurismal sac lay the stomach, the transverse arch of the colon, the pancreas, a portion of the spleen; and firmly adherent to the middle and inferior divisions, were portions of the jejunum and ileum intestines, the separation of which required the use of the scalpel. The semilunar ganglions, and the plexuses of nerves in the vicinity of the sac, were to a certain extent compressed during the dilatation of the sac. The origin of the aneurism was traced by slitting open the aorta at its posterior part, and was observed to commence from the front of the artery, immediately after its passage between the crura of the diaphragm. The aperture leading into the sac may be described as an oval-shaped longitudinal slit, measuring one inch in its vertical diameter, and from three to four lines in its transverse. The edges are rounded, smooth, glistening, and rigid; slightly puckered at the corners. The lining membrane of the artery is evidently continued through the aperture into the sac, and is perfectly free from a breach of continuity of surface.

The aneurismal pouch is capable of containing a large-sized orange, or globular body, from two to three inches in diameter, and is partially filled with fibrinous coagula, mixed with fluid and recently coagulated blood, collected in the inferior depending portion. The internal surface of the sac presents different shades of redness, with a rough uneven appearance, produced by the greater or less accumulation of fibrine coating the interior; which, when removed by the scalpel or nail, exposes the smooth, polished, glistening mem-

brane, continued from the artery into the sac. The coats of this aneurismal pouch present various degrees of density, their thickness being more apparent at the base than apex of the tumor, whilst an extreme degree of attenuation prevails at the inferior part, where the transverse rent has occurred. When first seen, it was blocked up by a portion of the fibrinous coagulum already alluded to. The density of the external cellular coat in this case was considerable. From the anterior and lateral aspects of the sac, the chief branches of the abdominal aorta, for the supply of the viscera, were given off. The cœliac axis, superior mesenteric, and renal arteries, sprung from the sac. The calibre of some of these vessels was dilated, and their coats thickened, indurated, and discoloured. The iliac arteries were healthy, as were also the various viscera in the abdomen.

The cavities of the heart were exhausted of blood, and firmly contracted. On the anterior aspect of the left ventricle a circular white spot was noticed, the pericardium being more dense, and partially corrugated. No disease prevailed in the valvular system. The internal surface of the aorta presented detached patches of redness, and loss of the polished shining appearance so apparent in the healthy vessel; its coats, also, were somewhat increased in thickness; its elasticity was retained.

Some engorgement of the posterior parts of the lungs, with adhesion of the pleuræ.

There are few diseases to which the human frame is subject more difficult of diagnosis, more involved in obscurity, than the incipient stage of abdominal aneurism; few in which, by the process of remotion, by a system of exclusion, and with the valuable aid of the stethoscope, we fail in arriving at a degree of certainty in our diagnosis except in this: but when we reflect on the extent of the abdominal cavity; the number of solid viscera contained therein; the deep-seated situation of this vessel; the variety of vessels, nerves, solid and hollow viscera, interposed between it and the surface of the integuments; from the liability of disease of one organ simulating, in its symptoms and physical signs, those of another, we must confess that the most skilful practitioners, the most experienced

stethoscopists, of the British, Irish, and Continental schools of medicine, have been, and will be, baffled in their diagnosis of this disease.

Can we, in the history and symptoms of the case, discover aught by which the diagnosis between incipient aneurism of the abdominal aorta, and acute or chronic affection of the viscera, may be facilitated? Can we, by an examination of the abdomen, detect any prominent tumor, isolate any particular organ, which may be fixed upon as the seat of disease? Can we not, in fine, by the aid of auscultation, point out a series of physical signs, peculiarly characteristic of lesions of the arterial tube in their early stage? Frequently not. In the present state of our information on this subject our reply must be in the negative.

In a paper published on this subject in the fourteenth volume of the *Dublin Journal of Medical Science*, Dr. Corrigan has directed the attention of the profession to a mode of detecting this disease in its early stage, by substituting the horizontal for the erect position, with the intent to remove the hydrostatic pressure of the arterial column of blood on the parietes of the sac, and so render distinct, physical signs previously inaudible. This suggestion of Dr. Corrigan has been adopted in several patients; in some attended with the happiest results, in others failing in an unaccountable manner—the presumptive evidence of the existence of an aneurism being as cogent in the latter as in the former: in such persons, as well as in those subjected to the experiment by Dr. Corrigan, there has been detected, after the free evacuation of the bowels, a circumscribed globular pulsating tumor, of greater or less size, generally situated in the epigastric and umbilical regions, with a slight lateral inclination.

Closely allied to this subject is one which embraces the consideration of the double arterial sound, audible in aneurismal lesions of these vessels, as an additional means in enabling us to detect the incipient stage of this disease: but previous to our commenting on the valuable aid afforded by this physical sign in the abnormal, we ought, for many reasons, to refer first to the physical signs furnished in the normal conditions of the arterial tubes.

Every person conversant with the

use of the stethoscope can convince himself of the presence of two distinct, separate, well-defined sounds in the arteries of large and small calibre, the individual recognition of which is much facilitated by an examination of the thoracic and abdominal aorta, from the greater degree of perfection in which they exist, and their true character being more readily ascertained. Of these, the one, which constitutes the first sound, imparts to the mind the idea of being comparatively dull and prolonged; synchronous with the first sound of the heart, and varying slightly in its character, according to the rapidity of the circulation. This sound has been considered to originate in the propulsion of the arterial column of blood from the ventricle, which, in its transit, impinges on the parietes of the arterial vessels.

Subsequent to this, a clear, sharp, abrupt, well-defined clack, constituting the second sound, is distinctly audible, proportionably loud over those vessels possessing the largest calibre, and accurately corresponding in character with that heard in the cardiac region, near the base of the heart, and hitherto considered as valvular in its nature; the validity of which theory I purpose to investigate anew, and subject to the analytical tests of pathological anatomy.

That a perfect knowledge of these facts is of the highest practical import may be illustrated by our reverting to the subject of incipient aneurism of the abdominal aorta.

A case is presented for our inspection wherein the symptoms are of that description as to excite our suspicions, and from negative evidence we are satisfied that disease of the viscera does not exist. If, in our manual and stethoscopic examinations, we notice an unusual degree of strength in the pulsations of the aorta, unaccompanied by abnormal murmurs, and unaffected by change of position;—if, in the course of the artery, we observe a circumscribed space, over which the normal sounds of the artery are preternaturally clear, unusually well defined—the first sound abnormally prolonged—the second sound clearer, sharper, and more distinct than in any other portion of the arterial tube;—if the pulsations and physical signs remain stationary, or become daily more developed, and the symptoms persist, despite our

treatment, but cannot be traced to an acute, subacute, or chronic affection of the viscera;—under these circumstances we are justified in inferring that a lesion of the arterial tunics exists, and an aneurismal pouch, in its incipient or rudimentary stage, has been formed, and is in progress of enlargement. In the more advanced forms, phenomena become apparent, and physical signs developed, which render unequivocal the diagnosis of this disease.

The principles to which I am anxious to direct attention, and, if possible, establish, may be more fully exemplified by a reference to the condition of the thoracic aorta,—aneurismal lesions, in their incipient stage, being involved in extreme obscurity, and liable to be mistaken for, or confounded with, other diseases, to which they bear not the slightest affinity. Thus, in two or three patients, who had been under treatment for several weeks, and were pronounced to be suffering from rheumatic pains in the neck and upper extremities, with anomalous symptoms connected with a morbid state of the pulmonary tissue, I have been induced to declare in favour of their originating in an aneurismal lesion of some portion of the arch of the aorta, in consequence of the following note being confirmed by daily examination:—"In the second intercostal space of the right side, about half an inch external to the sternum, is a clear, sharp, abrupt, unusually well-defined clack, not preceded by a whizzing murmur, but by a slight prolongation of the arterial first sound, which deviates not from the character of the normal sound except in its duration. In removing the stethoscope from this circumscribed space, the distinctness of these sounds gradually declines, so that they can scarcely be heard to the left of the sternum. In the cardiac region, the heart's action and sounds do not vary from those of a healthy organ, the frequency of the pulse ranging between 80 and 86. The second sound heard within the limits of the cardiac region, and at the base of the heart, possesses not that clear, sharp, abrupt clack, so obvious in the intercostal space. As soon as the circulation has become accelerated by their walking quickly through the wards, the arterial action increases in energy; the physical signs

are more extensively heard, but the relative proportion between the duration of the two sounds previously observed becomes less defined. In this stage of the disease there are no impulses communicated to the touch,—there are no phenomena,—no physical signs furnished by the venous circulation, none by the organs of respiration, none by those of deglutition;—all of which, in the subsequent, progressive, and more advanced stages, by contributing their respective quota, render the diagnosis of aneurismal lesions of the aorta practicable in the moderate enlargement of the sac, and prior to the formation of a pulsating tumor externally. That this appreciable alteration in the normal arterial sounds, unaccompanied by abnormal murmurs, did aid materially in enabling us to form a diagnosis, and were not imaginary on our part, nor they deceptive in their indications, was proved by the subsequent manifestation of symptoms, phenomena, and physical signs, which rendered unequivocal the existence of an aneurismal lesion of the aorta.

In the progressive dilatation of the aneurismal sac, the relative proportion previously observed to be maintained between the duration of the first and the predominating sharp abrupt clack of the second sound is in a great degree annulled, the first, assuming a duller, more prolonged character,—which change, in accordance with the views already stated, may be explained by the propulsion of a larger volume of blood into the interior of the sac, and the contact of its particles with a greater extent of surface; in some cases exempt from abnormal vibrations, in others presenting a variety of intonations, from the finest shade of the bellows-sound to the most intense description of the whizzing, buzzing, thrumming murmur. The corresponding alterations in the character of the aneurismal second sound proceed, *pari passu*, with the pathological changes in the structures of the arterial tunics, the middle coat in particular, and consist in a diminution of the clearness, sharpness, abruptness, of its characteristic clack; its distinctive vibrations, hitherto so obvious, becoming less defined; its occurrence and duration with the systolic action of the sac being more prolonged, in proportion as the density of the aneurismal sac in-

creases, as the hypertrophy of the fibres of the middle coat becomes more developed, and as the accumulation of a fibrinous deposit on the inner surface of the sac forms the successive layers of the coagulum.

These facts, and the observations hitherto recorded, tend to establish the theory, that the second sound is essentially arterial,—mainly dependent upon and principally produced by the action. The contractile power inherent in the middle tunie of the arteries of large calibre,—the semilunar valves bearing the same relation to the second sound as the auriculo-ventricular valves do to the first, viz. their structures remaining free from disease, they render it more perfect; by being diseased, they are instrumental in the production of murmurs which obscure or replace the normal arterial sounds; but complete disorganization of their structures may exist without any appreciable alteration in the character of the second sound, if the coats of the arteries suffer not from the pathological lesions described.

If this theory prove to be correct, and if it maintain its position after a scrutinizing investigation into its pretensions, it must refute and render invalid the adopted theory of the day, which pronounces the second sound to be valvular, produced by the reaction of the arterial columns of blood tightening the semilunar valves at the ventricular diastole.

PURPURA HÆMORRHAGICA.

To the Editor of the Medical Gazette.

SIR,

SHOULD the following case of purpura hæmorrhagica be considered of sufficient interest to merit a place in your valuable journal, an early insertion will much oblige,

Your obedient servant,

THOMAS STAINTHORPE,

Member of the Royal College of Surgeons,
London, and Licentiate of Apothecaries'
Hall.

Hexham, Northumberland,
Oct. 6, 1842.

William Hedley, ætat. four years, a healthy-looking, stout boy. Has enjoyed generally good health; was observed for some days to be dull, listless, and thirsty, with flushings and rigors.

On the 14th of August I was first called, and found him with some dark spots on his tongue, inside of cheeks, lips, and a few over the body. The bowels being constipated, I gave calomel and a saline aperient, which had to be repeated.

15th.—Skin almost covered with petechiæ, varying from bright red to purple colour: the largest nearly a quarter of an inch in diameter; tongue, gums, and fauces, same as yesterday; the spots not nearly so numerous as on the surface of body, but larger; has expectorated blood different times during the day; pulse 112, small; heart's action strong; tongue covered with a yellowish fur; skin hot; breathing quick; appetite very moderate; great thirst; a spot on conjunctiva of left eye. Ordered—

Balneum Tepid. maneque nocte.

℞ Acid. Sulph. Delut. ʒj.; Aq. Distill.
ʒvij. M. ft. capt. coch. j. parv. ter
die ex aq.

16th.—Petechiæ are of different shades; spot on conjunctiva larger, and discharging thin pale blood; pulse 116, small and quick; skin hot; urine scanty and muddy; passed some blood by stool; tongue less loaded. Ordered to wear a shade to exclude the light from the eye, and bathe it occasionally with tepid milk and water.

Cont. Alia.

17th.—Petechiæ going through the varied shades of red, purple, and yellowish colour; conjunctiva the same; pulse 120, fuller; tongue furred with white; bowels not open to-day; passed a pint of bloody urine, with pain in voiding; expectorated blood different times since yesterday; thin blood is discharged from the right nostril; no appetite.

Cont. Baln. Tepid.

℞ Hydr. Submur. gr. iij.; Pulv. Jalap.
gr. iv. ft. Pulv. Aper. statim sumendus.

℞ Acet. Plumb. gr. iij. ft. Pulv. Mitte
j. capt. unas post Pulv. Aper. h. s. et
alter. mane.

18th.—Petechiæ much the same as yesterday; a pint and a half of bloody urine; bowels open from the purgative; vomited the powders; skin pale and clammy; pulse 124, small and irregular; discharge from conjunctiva sanguino-purulent; hæmorrhage from nostril same as yesterday; very restless. The bath to be discontinued.

R Acet. Plumbi, gr. iij.; Pulv. Opil,
gr. $\frac{1}{2}$. ft. Pulv. mitte no. vj. cap. j.
3tia q. q. horâ. Vin. Rubri. Coch.
Parv. omni horâ.

19th.—No fresh petechiæ discoverable to-day; twenty ounces of bloody urine; bowels free; pulse 130, very irregular; other symptoms much the same, but appears to be sinking.

Rep. Vin. et Pulv.

20th.—Passed a better night; urine increased in quantity, with less proportion of blood; pulse a little steadier; no bleeding from the nostril.

Cont. omnia.

24th.—Has improved daily since last date under the wine and acetate of lead. Many of the spots have disappeared; what remain are diffused, of a purple and yellowish colour; urine contains a little blood; conjunctival discharge more purulent; pulse 116, soft and regular; lips and tongue pale and exsanguine; bowels open from an aperient yesterday.

Cont. Vin.; Rep. Pulv. cap. j. bis in die.

30th.—The symptoms have gradually improved since last date; urine quite clear; complains of debility; appetite improving.

Sept. 7th.—Quite well, but continues weak.

30th.—Enjoying his ordinary health.

REMARKS.—At my first visit the case was well marked, and not to be mistaken. The treatment, however, had no beneficial effect until the acetate of lead was combined with opium. The lead would not remain on the stomach by itself. On the 17th I was inclined to bleed from the arm; but the pulse, although fuller, did not indicate such treatment, nor was the heart's action at all strong (as we sometimes find the pulse may be small or weak, yet the heart's action strong and firm). The bath was discontinued, because the surface remained purple after it was taken on the morning of the 18th. There was slight tenderness on pressure over the right kidney, while the urine was mixed with blood. Perhaps it might have been better to prescribe the acetate of lead and opium at an earlier stage of the disease, which I would do were I to meet with another case of purpura.

CASE OF ALBUMINOUS URINE.

To the Editor of the Medical Gazette.

SIR,

As, in the examination of albuminous urine, the following circumstances had never been previously observed by me, and as similar might mislead a person unaware of them, the following practical hints as to the quantity of acid used may be worthy your notice.

Finding, on heating in a tube with a few drops of dilute nitric acid, some highly albuminous urine, that became a solid mass when heated by itself, and from which was thrown down a most abundant precipitate on addition of undiluted nitric acid, that it did not coagulate, but became only gelatinous, I was induced to examine the matter more attentively.

If to two fluid drachms of this urine a drop or two of dilute nitric acid be added, a light flocculent precipitate falls, which is entirely dissolved on shaking, and by heat the fluid coagulates; but if six or eight drops be added, the precipitate is likewise dissolved, while the fluid remains perfectly clear on boiling. By addition, however, of sufficient ammonia to neutralize the acid, coagulation occurs, though not as perfectly as if the urine had been heated alone. A larger quantity of the dilute acid causes the entire and permanent precipitation of the albumen.

Almost similar are the results of the admixture of dilute nitric acid with ovalbumen and healthy urine or water; also with the serum of the blood and healthy urine. On boiling some drops of acid with ovalbumen and water, an uniform opalescent jelly is formed, but no coagulation takes place. The action of the acid on a mixture of one-third serum and two-thirds healthy urine is precisely similar to that on albuminous urine, proving the source, and almost the simply physical transudation, of the extraneous matter.

The dilute acetic and oxalic acids do not impair the coagulability of the liquid, while neither the muriatic nor sulphuric acids precipitate the albumen when the fluid is cold; whereas, on boiling it with the former, an opalescent uniform jelly results, and with the latter acid the coagulation is not prevented.

If this crude notice of the varying action of the acids on albuminous fluids is worthy attention, the insertion in your journal will oblige, sir,

Your obedient servant,
JOHN S. BARTRUM.

Gay Street, Bath,
Oct. 7th, 1842.

OBSERVATIONS ON THE TREATMENT OF FRACTURES.

To the Editor of the Medical Gazette.

SIR,

IT IS NOW eight years (*vide* MEDICAL GAZETTE, vol. xiv. p. 670) since I first advocated the necessity of attending to the keeping up the action and temperature of the cutaneous structure in inflammation, laceration, or contusion of the cartilaginous, ligamentous, tendinous, fibrous, and muscular structures of the body, and since I also denounced in those affections the application of cold, and the diminution of power by means of local bleeding near the injured part. Experience has fully attested the many advantages of hot stimulating applications; they have a decided preference in lessening the sufferings of the patient; while, on the other hand, much time is gained in restoring the reparative action of the parts, notwithstanding that tumefaction, redness, and swelling of the cutaneous and subcutaneous structures generally proceed with great activity during the first four days, then gradually subside about the seventh or eighth day, leaving the deep-seated structures comparatively free from pain either on motion or pressure; and the truth of this will appear evident on reflection of the well-known Hunterian law, that no two inflammations can exist with equal force in the same system; the one will mitigate the other. Next, we must consider the lowly organized state of these structures, which are only balanced or supported in their normal action or temperature by the power of the exhalent vessels of the skin. Did these lower structures but contain one drachm of blood more than in their normal condition, the result would be inflammation, which would require three months at least to effect a termination by resolution. It is a fact, that excitement of the arteries in the vicinity of an injury

assists much in the restoration of a sanative action. Only diminish the power of the arteries and exhalents below the natural standard in such injuries, and you deprive the limb of the means of repairing the mischief, and too frequently bring on phlegmonous inflammation or sphacelus.

By this statement I do not mean to condemn the necessity of general depletion when the pulse is quick and hard; but I feel bold in asserting, that local bleeding by leeches, with the application of cold lotions, prevents the well-doing of such cases. The sole use, and a great one, of the diffusible stimuli, is in great weakness, where they are only required to support the system, while it cannot be supported by the ordinary durable stimuli; and after the excitement is so far restored that the ordinary supports are now sufficient to lay aside the extraordinary, the continuance of which would be hurtful, and to manage the convalescent and restored state of health by the powers employed in health. When the diffusible are continued longer, they are equally hurtful, and a cause of disease, as they are serviceable when disease requires their support; analogous to wine, they bring about the system, in a weakened state, so as to be sustained by its natural and ordinary supports; but analogous to it in another respect, when the strength of the system requires not their additional stimulus, they carry it up into indirect debility.

We must bear in mind the remarkable lowness of vitality in these structures. A cut or laceration of the tendinous or fibrous structures is attended with far less serious consequences than a false position that distends them. The natural temperature of the cartilaginous and tendinous parts is very low; for in general the degree of heat in an organ is proportionate to the quantity of blood-vessels it receives. If the erroneous systems of surgery that have appeared in the world could be reduced to any general point of agreement, it would be that there is not a mode of evacuation, or of impoverishing the several parts of the vascular system of their respective fluids, that the brains of practitioners have not been tortured to contrive and employ, forgetting that life is a forced state, that animals every instant of time tend

to death. A Roman poet has somewhere said—

“Wine, warmth, and love, our vigour drain;
Yet wine, warmth, love, our life sustain.”

We are apt to mistake the seat of pain, believing it to be in the lower structures, when in truth it has its seat in the cutaneous structure. The following case will afford some demonstration of the principles I have endeavoured to establish:—

— Meek, aged 45 years, fell from off a scaffold twenty-five feet in height, and received a fracture of the left temporal bone, and a compound comminuted fracture of the tibia and fibula, one-third from the knee-joint, about two inches below the insertion of the ligamentum patellæ. The nature of the fracture of the leg, with the injury to the surrounding parts, would have induced me to suggest amputation, had not the cerebral symptoms manifested a fatal tendency, viz. insensibility, with arterial bleeding from the left ear. The upper end of the fractured tibia was split and splintered at least one inch and a half. Having removed the rough fragments, I reduced the fracture, and placed it in one of my suspension apparatus, as described in the twelfth volume of the *MEDICAL GAZETTE*. After general depletion and counter-irritation, the cerebral symptoms gradually resumed a healthy state, about the third week from the time of the accident. Until the eighth day the leg appeared to be progressing rapidly, the ends remaining in apposition; but whether owing to the sacking of the bed giving way, or want of outer support to the thigh, the broken end of the upper part of the tibia projected, and sphacelus round the wound commenced. Despite of adjustment the end still protruded, as if from spasm. I again took off a large portion of the bone, and placed the leg in the straight position, with a long outer splint extending half way up the thigh, which had the effect of readjustment of the fracture. I then applied a hot poultice to the wound, which was continued until it healed; ordered a stimulating diet, with meat, &c.

The union by bone took place at the end of the seventh week, at which time the case was seen by two medical friends who happened to be at Cray-

ford, viz. Mr. Tuckett, of the Dreadnought Hospital Ship, and Mr. Alinson, of Woolwich, who were not a little surprised to see the bone consolidated. The case is an example of the benefit of country air and good diet in cases of compound fracture. At the end of the tenth week the patient was removed home, a distance of two miles: and here I observe, the immense difficulty of restoring the lost muscular action. He has now been more than seven weeks endeavouring, by the use of friction and action, to regain the use of the limb. Although he can now support the weight of his body on the leg, yet he is unable to walk without the assistance of a crutch and stick. I have frequently had my patients, who have had the thigh fractured, walking without support at the end of the eighth week. When the muscles have been kept so long on the stretch, or passive state, there is much difficulty in persuading the patient to use all his energies in obtaining a restorative action of the muscles.

I do not like to make any assertion without proof; but I cannot help thinking (and it is my intention to reduce it to practice when the next opportunity occurs) that galvanism applied moderately, and with the foot or hand immersed in hot water, would be highly beneficial in regaining the use of the suspended power of a limb. I beg leave to state my objection to the straight position in treatment of fractures of the thigh and leg. From the commencement of my surgical life I have been in the habit of placing fractured limbs in such a position, that the fewest muscles are rendered tense. In fractures of the thigh, notwithstanding the apparent simplicity and adaptability of Desault's splint, I am practically convinced that the patient who is treated in such a manner loses much time during the convalescent stage. The bone may unite; the limb may be rendered straight by its application; but, on a fair comparison with a proper double-inclined plane rightly adjusted, the patient will suffer far less pain in getting the limb accommodated to that passive form than by the extended position. Two things, therefore, are gained, a shorter duration of pain, and many weeks of time in the restoration of the muscular

action during the convalescent stage of a fracture.—I am, sir,

Your obedient servant,

JOHN GRANTHAM.

Crayford, Kent,
Oct 6, 1842.

P.S.—The splint that I use in fractures of the upper third of the tibia extends from the outer malleolus to the upper third of the os femoris, having a hinge-joint opposite the outer condyle of the os femoris. J. G.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Methodus Medendi; or, the Description and Treatment of the Principal Diseases incident to the Human Frame. By HENRY McCORMAC, M.D. Consulting Physician to the Belfast Hospital, and Professor of the Theory and Practice of Medicine to the Royal Belfast Institution. London: Longman, Brown, and Co. 1842.

A VERY great mass of information is contained in this volume—in fact, a whole system of medicine; but it is rather too much condensed—too much concentrated, to be very easy of digestion. The chapters have no headings, except of the very briefest kind, such as “Fever—Typhus,” and the index is little more than a list of diseases. These circumstances render the information it contains less accessible than is desirable; but still the matter is there, and in great abundance, if the reader have time and industry to seek it out. From this account it will be perceived that the work is better suited for the advanced student than the beginner, and to the former we earnestly recommend it, as he will find the facts which have been made out, and the opinions which are recorded, by almost every writer on the different branches of medicine whose sentiments are in any degree worth knowing. The nature of the work admits only of an opinion, and a specimen being given: above, we have expressed the former, and we subjoin the latter.

“Lesions after death are not constant: I have often not discovered any, or any adequate to the production of

death. Of those dying of what are termed essential fevers, observes Andral, the small, and, more frequently, the large intestines, are exempt from every change. Louis, Delmas, Cayol, Martinet, and Bouillaud, all record fatal instances without any local affection. The mucous membrane of the small intestines, writes Louis, in one instance, likewise the elliptic plates of the ileum, were free from all traces of alteration. Bouillaud and Chomel, and others, aver that the digestive tube was perfectly healthy; and Alison, Neumann, Gerhard, and Lombard, make similar admissions. Marks of gastric disease are far less frequent than the affirmations of Broussais, Bouisseau, Roche, Stokes, and others, would imply. Commonly there is no departure from the healthy state; sometimes, there is slight discoloration, occasionally softening and ulceration of the inner surface; alterations, however, not confined to fever, and very equivocal indications of inflammation. Softening, in particular, would seem merely a cadaveric change, and was often detected by Andral without the least evidence during life of its existence. In the twenty-first case of Chomel's Clinique, all three coats of the stomach were ready to slough out; and a pupil having placed his finger on the black spot, an aperture, through which fluid passed, quickly ensued. In four instances by Louis, the ulcers did not penetrate the mucous coat, and were from two to three lines in diameter. Alterations, not follicular, of the large and small intestines, are not numerous. A reddish tinge, confined to the mucous membrane, or extending to the three coats, is occasionally visible, even through the peritoneum; Chomel speaks of sanguineous infiltration with thickening, from a few inches, to as many feet, confined to the mucous coat. The hue varies from a rose colour to a reddish black, and fluid may be expressed by the handle of the scalpel. Blood, however, may be exhaled apart from ulceration or erosion. Softening and discoloration are not confined to the vicinity of the altered plates.

“The abnormal development of the mucous follicles of Peyer and Brunner, along with enlargement, induration, or softening of the corresponding mesenteric glands, are frequent occurrences in fever. These glands have been

seen large as a pigeon's egg, perhaps soft and tending to suppuration, of a red, violet, or blackish aspect. Louis found one near the cœcum, which had undergone purulent conversion by the forty-ninth day; and the parietes were so thin, that rupture and effusion, had the patient lived, could not have been remote. The glands contiguous to the altered plates are those principally affected. Sarcone, Rœderer, and Wagler, Prost, Broussais, Petit, and Serres, Andral, Bretonneau, and Louis, describe the alterations here adverted to, while they are pourtrayed in the plates of Baillie, Cruveilhier, Carswell, Hope, and Bright. The plates or agglomerated follicles of Peyer, when affected with disease, are of an oval form, often apparent through the coats of the intestines. The term dothineritis, meaning pustular enteritis, has, in such cases, been applied. The cœcum and close of the ileum, being the principal seat of the plates, are the parts mostly affected; the isolated follicles, or those of Brunner, may be similarly implicated. In colour, the eruption alternates from white to red, along with that of the adjacent mucous membrane; the consistence, also, is variable. The dimensions may be from two to three square inches or larger, till they dwindle to a single follicle. The plates are seated opposite the insertion of the mesentery, but the single follicles occupy every part indifferently. In the large intestines, the plates are smaller, whereas the follicles, those in the rectum excepted, are larger, as well as more numerous. The number of plates varies from one to twenty, but the amount of the follicles is quite uncertain. Orifices are discoverable on examination, but the several mucous crypts may be so closely blended together as not to be separately distinguishable. The muciparous glands, as they are also termed, may undergo resolution, or proceed to gangrene and ulceration. In the first case, they gradually lose their prominence, and assume their wonted healthy aspect. What the French term *plaques gangrénées*, that is to say, plates in the first stage of alteration, are the only ones which undergo resolution: in the reticulated plates, *plaques réticulées*, partial gangrene has already commenced. It has not been determined whether sloughing be a necessary precursor of ulceration,

whether the latter take place at other points besides the altered follicles, or whether it ever extend beyond them. Ulceration sets in about the tenth day, and is much less frequent in the isolated, than the agminated follicles. The sloughs involve the mucous coat, or both mucous and muscular coats, and may come away in soft fragments or debris, or single masses of a greenish yellow hue. The ulcers are oval or round, much as if punched out; often they run together, so as to involve a considerable portion of the mucous membrane. When the slough is detached, the submucous cellular tissue, or even the peritoneal coat, forms the base of the ulcer. Should complete perforation ensue, inflammation and death are the almost inevitable result. The communication, Louis informs us, rarely exceeds three lines breadth; it almost invariably occurs at the termination of the ileum. Intestinal cicatrices differ less from the surrounding mucous tissue, than those of the surface do from the skin; they even, it is said, disappear, the normal tissue being reproduced, or a kind of serous membrane or pellicle is substituted.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

HOW TO PROCURE SLEEP.

WHEN Martial drew that celebrated picture of a happy life in which he has accumulated every circumstance of ease—the estate not earned, but inherited—good health—a cheerful wife—and friends of one's own station, he did not forget the *somnus qui faciat breves tenebras*. Without sleep, the period of darkness is long indeed; or, as Madame de Sévigné expresses it, there are twelve hours in the day, and fifty in the night.

Perhaps Abernethy's receipt for curing the gout, by living on a shilling a day, and working for it, might prove

equally efficacious against watchfulness; but the remedy is far from being a popular one. Hence, in all ages, the rich and luxurious, unwilling to purchase repose by exertion, have harassed physicians with demands for sleep; and the list of prescriptions for the wakeful is endless.

Dr. Binns, who has lately published an amusing work on the subject*, thinks that medicinal narcotics were preceded by other means. "The murmur of the ocean, the warbling of birds, the voice of woman, the melody of flutes, the monotonous fall of water, the narration of fables, and the luxurious prostration of the warm-bath, were, at the earlier periods of human history, and are, even now, in the East, resorted to, to procure oblivion of existence."

However this may be, it is certain that much more powerful narcotics have been employed from very remote ages. Wine is as ancient as the Flood, and opium probably not much younger than the poppy.

Dr. Thomas Young, in the list of *Materia Medica* with which he has enriched his "Medical Literature," has divided narcotics into three classes. In the first, among narcotics of undoubted power, there are two which one is surprised to see there—musk, and the syrup of the red poppy. In the second are camphor, digitalis, wine, and rectified spirit. In the third, we find lettuce, the smoke of stramonium, *calor modicus*, and *frigus summum*. We have not the book before us, and do not recollect whether *cocculus indicus* is in either of the classes; but perhaps it may be considered as included under the head of *Porter*, which occurs in the third. Last of all, in a parenthesis

by itself, we find ("Counting 1000, or rather, 100 respirations").

This counting is in principle the same as several other methods of inducing sleep by monotony:

Fontesque lymphis obstreptant manantibus,
Sonnos quod invitet leves.

HOR. *Epod.* ii. 27.

Among the remedies for watchfulness, Darwin gives, in his *Zoonomia*, "an uniform sound, as of a pausing drop of water, or the murmur of bees*." "From the remotest ages," says Dr. Binns, "poets have celebrated the murmur of brooks, the waving of a field of corn, the ceaseless splash of ocean, the whispering of groves, the hum of bees, in short, monotonism, as incitements to repose; while the venerable Wordsworth adds, the continued passage of a flock of sheep, the passing of a herd of oxen, a flight of birds, and even the ocean, as he styles it, 'a grand monotonous idea.'"

Boerhaave, again, in a case of wakefulness, ordered water to be placed near the patient, so as to drop into a brass pan. Dr. Willich, who wrote some forty years since, knew that sleep was promoted by "gently and uniformly affecting one of the senses; for instance, by music or reading." Mr. Maenish often coaxed himself to sleep by repeating some well-known rhyme half a dozen times; and a gentleman, in the town of Milford, has learned to fall asleep at will, by fixing his eyes in one direction for a few minutes.

Dr. Elliotson knows a lady who often

* The following example might be attributed to monotony, or more correctly, as it is by Darwin, to compression of the brain:—"Another way of procuring sleep mechanically was related to me by Mr. Brindley, the famous canal engineer, who was brought up to the business of a mill-wright: he told me that he had more than once seen the experiment of a man extending himself across the large stone of a corn-mill; and that, by gradually letting the stone whirl, the man fell asleep before the stone had gained its full velocity, and he supposed would have died without pain by the continuance or increase of the motion. In this case the centrifugal motion of the head and feet must accumulate the blood in both those extremities of the body, and thus compress the brain."

* "The Anatomy of Sleep; or the art of procuring sound and refreshing slumber at will. By Edward Binns, M.D. &c."

It seems that this book was composed by a machine; we wish that the ingenious apparatus had thought of adding running titles and a table of contents.

remains awake till her husband rubs her foot; and to many persons the having their hair combed is a soporific. John Philips, the poet, delighted, when a boy, to have this office performed for hours together; and Isaac Vossius was so critically curious in combing, that he preferred its performance rhythmically. He liked to have it done by barbers or other persons skilled in prosody, so that their pectinating movements might imitate iambs, trochees, &c. to his great delight. In these cases, reverie rather than sleep was produced; but in other instances the effect is that of a simple narcotic. Thus, Sir John Rennie, the architect, was regularly put to sleep by having the hair at the back of his head combed, and rubbed with the palm of the hand. In the West Indies, persons are often lulled to sleep by fanning, which is generally performed, says Dr. Binns, with a leaf of the *Coccoloba uvifera*, or seaside grape. Here again, the monotonous waving of the fan withdraws the attention of the patient from all disturbing thoughts, and from all external objects, save itself, and thus produces that one-toned impression which is inevitably and speedily followed by sleep.

"As the immediate cause of sleep," says Dr. Darwin, "consists in the suspension of volition, it follows that whatever diminishes the general quantity of sensorial power, or derives it from the faculty of volition, will constitute a remote cause of sleep; such as fatigue from mental or muscular exertion, which diminishes the general quantity of sensorial power; or by an increase of the sensorial power, as by attending to soft music," &c. (*Zoonomia*, vol. i. sect. 20, xviii.)

When we are told to procure sleep by an effort of volition, as, for instance, by imagining that we hear the murmur of an overshadowed fountain, or see the waving of a field of corn

when ruffled by the evening breeze, the plan seems in direct contradiction to Darwin's theory that the immediate cause of sleep is the suspension of volition. But, in truth, though it might require a powerful effort of the will to withdraw the mind from its ordinary anxieties to these agreeable images, yet when it is once engaged in them, volition yields to sensation; just as it may demand much exertion to climb a garden wall, yet the labour once achieved may be rewarded by repose among flowers.

Perhaps the faculty of voluntary sleep possessed by some few men may consist in the power of instantaneously abstracting the mind from all but the most monotonous stimuli. Thus Napoleon, according to Bourrienne, fell asleep in an instant, while sitting by the side of Alexander, of Russia, and witnessing the representation of the *Cid*. Sir William Cockburn, of Bath, is likewise said to enjoy this faculty.

The removal of irritation or stimulus ranks next to monotony, or perhaps, above it, as a means of procuring sleep. Thus, the Chinese recommend us to divest the mind of all unpleasant images, a counsel which we have touched on above, as the necessary preliminary to the uniform flow of agreeable ones.

Dr. Franklin's advice to a young lady on the art of procuring pleasant dreams, is chiefly grounded on the removal of uneasy physical impressions. Chiefly, we say, for he also recommends her to have a good conscience. He discountenances hearty suppers after full dinners; speaks of the disposition of the pillow; and advises the limbs to be placed so as not to press one another inconveniently, as, for instance, the ankles; for the resulting uneasiness may come on during sleep. The whole of the letter, which bears the stamp of Franklin's distinguished

good sense, may be considered a valuable contribution to the art of going to sleep, as well as of sleeping soundly. His recommendation of having two beds, one to be used when the other grows hot, is judicious, and might be followed by many with advantage, in sultry weather.

Under this head we might mention the proposal of Dr. Beddoes. He thought it better to cause sleep by abstracting stimuli than by exhausting excitability, and accordingly proposed to place the wakeful patient in an atmosphere containing a diminished proportion of oxygen, and to let in common air when he was asleep.

Dr. Binns very properly insists on removing several sources of irritation or discomfort, as a preliminary to sleep. Thus, the body may be sponged and then rubbed with a coarse towel before retiring to rest. The friction will certainly be beneficial, but we question whether the sponging and consequent evaporation is desirable for a delicate patient in cold weather. This general recommendation of sponging in England has arisen, no doubt, from our singular neglect of bathing. But why not supply the defect?

If sleep is prevented by cold feet, put a blanket at the bottom of the bed, between the sheets; or rub the feet with a wet towel, and then put on worsted socks.

The bed-room should be large and airy, and in winter must have a fire. Dr. Binns thinks it a remnant of "barbaric ignorance" to go from a sitting-room heated to seventy or eighty degrees to a bed-room where water freezes. But, in the first place, we should call it more than a *remnant* of ignorance to heat the drawing-room to seventy or eighty of Fahrenheit: secondly, the sleeper is under more favourable circumstances for retaining caloric in bed, than on his Trafalgar

chair; and thirdly, in comfortable families, who enjoy the

Mundus victus, non deficiente cramenâ,
fires in bed-rooms are very usual.

Dr. Binns talks of savings in the doctor's and the butcher's bill, through this additional warmth; but at this end of the island the coal-merchant's account is an object of more terror to the humble middle-class-man than he imagines. We are of opinion that the *calor modicus* in another form is an excellent expedient; a warm bath, at 95° or 96°, for twenty minutes, will soothe many a watcher into sleep.

On the other hand, in very hot weather, a cold bath, and especially the agreeable fatigue produced by swimming, will be of service:—

*Ter uncti
Transnato Tiberim, somno quibus est opus alto.*
Hor. Sat. ij. l. 7.

Or the cheerful glass mentioned in the next line, in all its varied forms, from a goblet of Lafitte to an Oxford night-cap, may produce the wished-for end; but obviously is more liable to be abused than the other remedies.

"After supper walk a mile," says the old adage; and this, too, may be considered a narcotic. Several of these expedients, however, demand some little exertion on the part of the *dormituriënt*; and it is difficult to persuade easy self-indulgent people to put their own shoulders to the wheel, however urgent the occasion, or however manifest the benefit; they wish their snuffers to be not only patent, but self-acting.

An agreeable incident is given by It is in one of Mackenzie's novels, we believe, that an agreeable incident is given, which we have seen quoted somewhere as an example of sleep produced by monotony, but which we should explain differently.

The hero, having come to London, is so excited by the noise, that he is unable to sleep, until he accidentally touches his buckle, which is lying on

the table. The twanging sound produced reminds him of the voice of his aunt in the country, and volition is immediately suspended, as Darwin might have said. We should refer the effect, not to the hum elicited, which could neither have been long, nor loud, but to the power of association, which, by transporting him to his native village, freed him from the noises around, and delivered him up to the dominion of a single sensation.

Let the bad sleeper, then, endeavour to supply the place of this harmonious buckle; and instead of meditating on bad debts and the income-tax, the recent flight of his apprentice and his own incipient bronchitis, let him conjure up the farm-house in which he was born, the gayest scenery of the countries he has visited, or the still brighter pictures of the poets.

Should all these methods fail, there remains the discovery of Mr. Gardner, the "hypnologist," now published by Dr. Binns.

"Let him turn on his right side, place his head comfortably on the pillow, so that it exactly occupies the angle a line drawn from the head to the shoulders would form, and then, slightly closing his lips, take rather a full inspiration, breathing as much as he possibly can through the nostrils. This, however, is not absolutely necessary, as some persons breathe always through their mouths during sleep, and rest as sound as those who do not. Having taken a full inspiration, the lungs are then to be left to their own action—that is, the respiration is neither to be accelerated nor retarded. The attention must now be fixed upon the action in which the patient is engaged. He must depict to himself that he sees the breath passing from his nostrils in a continuous stream." The very instant he succeeds in doing this, he falls asleep!

SOCIETY FOR RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN

IN LONDON AND ITS VICINITY.

A HALF-YEARLY General Court of the members of this Society was held on Wednesday, the 5th instant, at the Gray's Inn Coffee-House, Holborn, for the confirmation of minutes, and the election of officers. It was presided over by Martin Ware, Esq. one of the Vice-Presidents, and was attended by Sir Charles M. Clarke, Bart., Dr. Warburton, Dr. Merriman, Mr. Stone, Mr. Ridout, and many other members.

It appeared from the Auditor's Report, that the income of the past year was £1845. 12s. 3d.; and the disbursements, £1433. 8s. 7d. The balance in the Treasurer's hands, £26. 11s. 8d.; and the sum added to the capital stock, £385. 12s.

The income arose, 1st, from life subscriptions and compositions of members, £103. 19s.; which, being in lieu of their annual subscriptions, must always be funded or added to the capital stock.

From benefactions and donations, partly annual, but principally casual, £172 17 6
2d, Annual subscriptions of members 285 12 0
3d, From dividends 1283 3 9

Available for current service of the society £1741 13 3

The disbursements were—
Grants for relief. £1285 10 0
Salaries 77 15 0
Other expenses, including those incurred during the late revision of the laws 70 3 7
£1433 8 7

The grants for relief have been distributed among 32 widows and 14 children of deceased members. Three of the orphans are adults, and have been relieved, not strictly according to the principles of the society, but on account of insanity or imbecility. The possession of £50 per annum from other sources disqualifies a widow, and £25 per annum a child, from receiving relief from the fund; but the majority possess much less than this sum. Fourteen (or nearly one-half) of the widows, and almost all the children, have no other dependence whatever. Three, otherwise unprovided for, receive £20 per annum from the Society of Apothecaries, which also makes a donation to the Society of fifteen guineas annually.

The Society for Relief of Widows and Orphans in London and its vicinity has now existed 54 years. In 1794, six years from

its foundation, and with a capital of less than £4000, the Court of Directors began to grant relief to distressed applicants. The following year £60 was voted for that purpose. Since then the capital has steadily accumulated, and the number and amount of grants has been progressively increased, until, in the year 1840, the capital amounted to £34,589 stock in the three per cents., and a small sum, less than £400, in the new 3½ per cents.

In that year too (1840) the trust for a reserved fund of £3500 new 3½ per cents., which in 1818 was set apart at compound interest for 21 years, expired, having accumulated to £7355—making the total capital £42,000, while about £28,000 had been distributed among persons eligible to receive relief.

On a minute inquiry into the financial affairs of the Society in 1840-41, arising from the question of the disposal of the accumulating fund, it became evident that notwithstanding the general prudence and wise management which had conducted these large financial proceedings with such gratifying results, the grants were then exceeding, and had of late exceeded, what could fairly be counted on as the available income of the Society, and that the due proportion, which the increasing capital had long steadily borne, and should always bear to the increasing expenditure, had been lost sight of. The timely detection of this error, by the vigilance of Dr. Burrows, a Director, soon led to its redress, and it was resolved to grant smaller sums to future applicants, and not to diminish the usual allowance to those already receiving relief, who would have felt severely any reduction of their scanty income. The two last years, therefore, have presented a decrease in the amount of grants; for although seven new applicants, five widows and two children, have been added to the list, they have been on the reduced scale of £30. per annum, while those removed by death were on the previous scale of £35 per annum.

It was early calculated that the number of applicants would gradually increase, and would reach its maximum, 70 or 80 years from the foundation of the Society. The first part of the prediction has proved true hitherto; and it is abundantly evident that the strain is just beginning to be felt, and that careful provision must be made to meet it. The laws have been thoroughly revised; some wholesome clauses have been added, graduating the life subscriptions of new members according to their age, and extending the term of annual subscription from 20 to 25 years; and a recurrence and rigid adherence to sound principles in the increase of the capital has been determined on, as well as

the strict application of the proceeds to the specific objects of the Society, viz., the "granting relief to the widows and to the orphans, under fourteen years of age, of its deceased members, who, upon application, shall be considered as needing and deserving of pecuniary assistance."

The Society has been enrolled agreeably to the Acts of Parliament now regulating friendly societies, and will profit by the increased rate of interest allowed by the Commissioners for the Reduction of the National Debt, and by the other privileges conceded to these societies when duly enrolled.

One widow and six children have been added since the audit in September to the list of pensioners; and three applicants, in great distress, were declared ineligible for relief: their husbands not having been members.

Five arbitrators were elected—viz. the Rev. Samuel Wix, Col. Cooke, B. Bond Cabbell, J. Tidd Pratt, and R. B. Upton, Esquires. Dr. Mann Burrows was chosen a vice-president in the room of the late Dr. Frampton. Dr. Watson and Dr. Roots, Messrs. Stone, Blagden, Annandale, Reeve, and Michell, were chosen directors in the room of six directors retiring in rotation, and of Mr. Lloyd Jones deceased.

It appeared on the minutes that thanks had been voted to the committee who had presented to the Society several engravings from their portrait of Bransby B. Cooper, Esq., that some copies had been sold, and that the rest might be obtained at Messrs. Paul and Dominic Colnaghi's, or on application to the secretary or collector.

EFFECTS OF DIVING ON THE HUMAN BODY.

JOHN WILLIAMS, private, Royal Sappers and Miners, aged 26, of great strength and activity, but addicted to habits of intemperance, has been employed during the last two summers on the wreck of the Royal George at Spithead, as a diver, and is considered one of the most expert workmen. On the morning of the 11th July, 1842, clothed in his submarine armour, he was engaged at the bottom of the sea, at a depth of 80 feet from its surface, in fastening an iron chain round a block of wood, that was imbedded in the stiff mud; which task, after an hour's labour, he had just completed, when the flexible tube that supplied him with air suddenly burst above water, with a loud hissing noise, which was distinctly heard at the distance of fifty fathoms.

While the divers are employed in their laborious search under water, the utmost

vigilance is exercised by those on the deck of the hulk, to prevent or remedy any thing that might endanger the diver's life, or interrupt his operations. The persons, accordingly, who were stationed at the air-tube and life-line, by which the divers are assisted in their ascent, immediately perceived the accident that had happened, and one of them closed the hole in the tube with his hand. Williams was promptly hauled up, but his armour got entangled in the heavy rope-ladder by which the divers descend, and he and it were pulled up together, in the space of about a minute and a half from the occurrence of the accident.

On removing the helmet from his head, blood was seen running in a stream from his ears, nose, and mouth. His face and neck were swollen and discoloured; he looked faint, but was sensible. In this state he was conveyed to the hospital, where he arrived in an hour after the accident. His face then was one mass of lividity; his neck was excessively swollen, bloated, and suffused with livid-coloured blood. Dark patches of ecchymosis that did not coalesce existed over the clavicle and shoulders, with intervening spaces of skin of the natural colour. The lower part of the neck, which had been covered with the flannel and India-rubber dress, was mottled black and white; the dark ecchymosis being raised in lines, with slight streaks of white skin interposed. The livid discoloration of the face extended upwards to, but did not pervade the hairy scalp, where it terminated abruptly; nor were any spots seen below that part of the chest which was covered by the helmet. The lining membrane of the cheeks, under the tongue, over the fauces and pharynx, as far as the eye could reach, but especially over the tonsils, was black with ecchymosis. The conjunctivæ, where they are uncovered by the eyelids, and particularly round the margin of the corneæ, were turgid with black blood. He vomited some blood before he reached the hospital, and he afterwards made occasional efforts to vomit, apparently from the accumulation of blood in the fauces, which blood he now and then expectorated. The hæmorrhage had ceased from the nose and ears, which were still covered with clotted blood. He was perfectly sensible, but seemed drowsy; pulse 76, of natural strength; breathing interrupted by frequent, deep, involuntary sighs.

Lieut. Hutchinson, who was present when the accident happened, and who accompanied Williams to the hospital, said that the swelling of the face and neck had much increased, and the lividity had much deepened, during the hour that had elapsed since he left the hulk.

In the course of the same day, the lividity of the nose and point of the chin vanished,

and those parts resumed their natural colour. The colour of the face too became much paler in proportion as the vessels recovered their freedom and diameter; but there were large patches of extravasated blood in the eyes, mouth, face, and neck, which could only be removed by the tedious process of absorption. On his admission, warmth was applied to his extremities; some warm tea was given him, which he swallowed with the greatest difficulty; he had a turpentine enema; and in the course of the day twenty ounces of blood were taken from the arm. The following morning a senna draught was prescribed, which has been occasionally given since. He has complained of occasional headache and dimness of sight, from which he is now free. The swelling and ecchymosis of the face and neck have daily diminished; and these parts have now attained their natural size and colour, showing that they were swollen on his admission to twice their natural size. The ecchymoses under the conjunctivæ were very tardily absorbed, and minute clots were visible for three weeks around the union of the cornea and sclerotic coat.

A similar accident occurred, under the same circumstances, about twelve months ago, to private Roderick Cameron, of the same corps, whose head, neck, and eyes, were discoloured in the same way; an account of which has been read to the British Association by Dr. Richardson. When Cameron was hauled up on the hulk's deck, he had lost all consciousness, and was in a state of apparent asphyxia, from which he soon recovered. A little blood only escaped from his nose; and none from his ears or mouth. At the expiration of a month, the ecchymoses under the conjunctivæ—that remained the longest—had disappeared; and undaunted by the perilous accident which had jeopardized his life, he returned to his work as a diver, which occupation he still fearlessly follows. Williams too is undismayed by his frightful accident, and he has resolutely returned to pursue his adventurous life, feeling confident that the prudent application of those precautions which are now well known will secure him from danger.

An accident somewhat analogous, as far as I can make out the facts, occurred to a diver at the wreck of H.M.S. Thetis, in South America, who, with a companion, had descended in a diving-bell. In this case, also, the air-tube burst, and one of the men immediately extricated himself from the diving-bell, and rose to the surface of the water unhurt. The other man, by some means, got entangled, and was some time in freeing himself from the bell, which he at length accomplished by the aid of his companion, who again descended for the purpose. When he reached the surface of the

water he was much exhausted, and his face and body were blackened with ecchymosis down to the waist. This discoloration gradually went off in the course of a month, the blackness of the balls of the eyes being the last to disappear.

These curious and strikingly similar effects of the same kind of accident at Spit-head seem to arise from the sudden removal of the compressed air, and the consequent exertion of the pressure of the superincumbent water on those parts of the body which are not covered by the unyielding helmet. It is calculated, in round numbers, that the pressure of the water on Williams's body, at the depth of his submersion, at the time of the accident, was nearly equal to the weight of three atmospheres, which pressure was counteracted, and the equilibrium preserved, by throwing air through a forcing-pump, of great power, along a flexible tube into his helmet. This supply of air is steadily kept up, by constant regulated pumping, during the whole time the diver is under water; and until the centre lens of the helmet is opened on deck. The quantity of air thrown along the tube into the helmet far exceeds what is required to sustain easy respiration and the equilibrium of pressure; but no harm can result from any additional quantity of air that may be forced in; inasmuch as the superfluous air readily escapes into the sea, by a valve in the helmet, and is seen constantly bubbling up on the surface of the water. When the tube burst, and the air escaped from the helmet, this equilibrium of pressure and resistance was destroyed. The head was protected by the strong helmet, which did not collapse, from the pressure of the circumambient water, which now acted on the rest of the body with a force equal to two atmospheres, and produced a feeling, as he expressed it, as if he had been crushed to pieces by his dress. The blood thus driven from the extremities and from those parts of the body that were not covered by the helmet, was forced into the vessels of the head and neck (as it is into a part of the skin placed under a cupping-glass) some of which blood remained in the vessels and disappeared in a few hours after the accident; but a large portion was extravasated in the loose textures into which it had been forcibly driven.

Six divers have been employed, during the last three summers, on the wreck of the Royal George. They have now nearly succeeded in clearing it away, and the anchorage has been, in part, restored to its former security, with fewer accidents, and none of them fatal, than it is likely would have occurred in similar operations, during the same space, above water. The value and importance of these operations, and the extent to

which they may be applied in recovering treasure, or in the destruction of important works on an enemy's coast, are still imperfectly understood, but General Paisley has satisfactorily established that these sub-aqueous operations may be accomplished at any ordinary depth, with ease and safety, by men who are not professed divers, and who have not been trained up from their infancy to the art. The divers engaged at the Royal George have been selected from the corps of Royal Sappers and Miners, whose characters and abilities as steady men and good workmen were known to their officers: but only some of those so selected have become good divers; for the effects of protracted submersion are so different in different individuals, that it is not every man who can follow the perilous life of a diver. Many experience intense pain in the ears, and bleeding at the nose, during their descent; and Lieut. Hutchinson, who ably conducts the operations on the Royal George, always experiences these sensations, and he has never been able to remain under water for any length of time. Those who are accustomed to dive successfully, never suffer any such inconvenience, and I cannot learn that they experience any very marked uneasy sensation, unless an occasional sense of nausea, or distension at the stomach, headache, and rheumatism; but they all agree that they are much weakened and wasted by the exertion, and, as they express it, are not the men they were when they began the occupation. I have not had sufficient experience to determine whether it renders them permanently unhealthy or short lived.

The diving season commences in May and ends in October, and the divers are usually employed eight or ten hours in the twenty-four. No scene can be more striking than the activity that prevades the hulk during the immersion of the divers. The busy groups of pumpers, on whose regulated exertions the lives of the divers depend; the deep groanings of the air-pumps; the anxious care that the men stationed over the hulk's side, with the air-hose and life-line in their hands, bestow on the preconcerted signals, by which the divers communicate their wants with the precision of speech; the turbulent agitation of active ebullition, that is occasioned by the forced escape of the compressed air through the sea; the dreadful plunge and rapid disappearance of the enormous and unwieldy mass in this boiling cauldron; the eager look of expectation and vague apprehension, with which the spectators gaze on the whole process, exceed in interest any thing I have ever witnessed.

The divers remain under water, according to the nature of their work, from half an hour to three hours; and although, in order

to accelerate their descent, they are heavily laden, with ponderous shoes and large leaden weights on their shoulders, constituting a dress of a hundred and thirty pounds weight, they move about nimbly at the bottom of the sea, and feel and work as lightly as if they had nothing on their shoulders and feet.

Mr. Richard Tilston has kindly made a very correct drawing of Williams's appearance when he was brought to the hospital; to which he has added a faithful picture of him, in his working dress, at the time the accident occurred, in order to convey a notion of his mode of groping his way under water, with his pricker in one hand and dog in the other. In these submarine expeditions the divers frequently encounter each other. On one occasion, three of them, from two different hulks, met, joined hands in a circle, and gave three hearty cheers at this triumph of the art of diving. On other occasions, however, their meetings are less friendly; disputes arise as to their claims to particular logs of wood, quarrels and sparring ensue, in which their large iron prickers play the part of single-sticks.

Nothing can exceed the spirit and industry with which these operations have been conducted, or the laudable emulation displayed by the workmen to excel each other in the quantity of work they severally perform; and nothing has occurred to damp their ardour until lately, when Corporal Jones, one of the most courageous and useful divers, met at the foot of his ladder a dead body, which produced such a shock, that he immediately ascended in the greatest possible alarm; and spoke as if he had encountered a supernatural being. Unsuccessful attempts were made to rake the body up from below; but a few nights afterwards it was brought up by Corporal Harris, the most intelligent and persevering of the corps, on his pricker, without his knowing what he had got hold of. His consternation when he reached the surface, and found that it was a dead body, was so great, that he could not go down again, and he was replaced by another diver, who not having felt his horror, was not unwilling to descend.

The divers are employed four hours at a time during the slack tide of low water, and in that space they usually descend about four times. On their ascent after an hour's submersion, they appeared to me, while they were leaning against the hulk's side, to be pale, languid, and exhausted, though they did not admit that they were fatigued. When they reach the top of the ladder, the centre lens is unscrewed, their ponderous helmet is taken off, and they are generally allowed ten minutes to recruit, while the wood they may have collected is drawn up by a crane. They can only work

two hours, at the slack tide of high water, in consequence of the strength with which the tide ebbs and flows at that period, which, they say, begins earlier, and runs with much more rapidity, at the bottom than at the surface of the sea, and which would carry them off their legs. They are also sometimes interrupted by storms, that would prevent their signals from being understood by those who attend the air-pipes and lifelines on the hulk's deck.

The divers are clothed in flannel dresses, that fit closely, which retain the warmth of the body and prevent the chill that might be produced by the soaking of the water through the seams of the India rubber dress. This dress is protected on the outside by a canvas covering, from any injury it might sustain by rubbing against the nails or ragged pieces of the wreck.

We know little of the effects produced by the respiration of compressed air, but the divers find that they can breathe easily at the bottom of the sea; they can sing readily, but cannot whistle. They converse with each other, by shouting at the top of their voice, which they hear in a whisper.

Each diver is paid, besides his regimental day pay of one shilling and three-pence, two shillings a tide, working three tides in the twenty-four hours.

Since the occurrence of Williams's accident, each diver has been furnished with a safety-valve, placed between the end of the air-pipe and the helmet. The air being forced in from the pump, opens the valve, and passes into the dress, but the moment this pressure is removed, the valve closes and prevents any air in the helmet returning through the pipe. This contrivance, however, I fear, in the event of an accident, would only substitute suffocation for that of being squeezed to death. — *Letter from Mr. Liddell in the Medico-Chirurgical Review*

OF SPUTA.

THE mucus ejected from coughing differs according to the character, extent, and stage of the pathological process; hence I shall first speak of the sputa from normal inflammation; secondly, of sputa from anomalous inflammation, and also on the appearance of sputa produced by the tubercular process.

Of sputa generated by normal inflammation.—Sputa produced in the commencement of a catarrhal affection of the air-passages, are found to be white, pellucid, thin, easily drawn into threads, and here and there they disclose within themselves a few small flocculent greyish nubes. The quantity of these sputa bears a direct relation with the extent of the pathological process.

Investigated by the aid of the microscope, the white pellucid fluid contains a very few round globules, filled with primitive molecules, and many cells of nucleated epithelium; the globules as well as the cells appear immersed in the pellucid fluid (proper mucus), but the greyish flocculiare composed of copious round globules filled with primitive molecules, and linked together with the proper mucus.

The catarrhal process increasing, the greyish flocculi receive an increase, which at length, from a yellowish-white, become tinged of a deeper yellow colour; the more the flocculi increase, the more the quantity of white fluid mucus decreases, the sputa becoming globose, and extremely tenacious.

The flocculi, investigated under the microscope, are composed of round globules filled with primitive molecules and a central vesicle. These globules appear linked with extremely tenacious mucus; but the white mucus (properly mucus), is a white amorphous substance, easily drawn into pellucid threads, which disclose cells of nucleated epithelium, and a few globules of a yellowish-white colour, endowed with the smallest molecules and a central nucleus. The inflammatory process decreasing, the quantity of globular sputa decreases; they acquire a somewhat whitish colour, until, the inflammatory process being finished, all yellow secretion ceases.

Microscopico-chemical investigation.—The globules contained in yellow mucus consist of smooth, very thin envelopes, in which again primitive molecules, and a single or double central vesicle are seen. The magnitude of the globules exceeds by six or eight times that of the blood-discs; but the diameter of the central vesicles scarcely equals it.

Globules exposed to distilled water increase in volume, although they may all have been freed from the adhering mucus; the envelopes break, the central vesicles and primitive molecules remaining.

Acetic acid, 1,030, dissolves the envelopes and primitive molecules, but the central vesicles remain intact; aye, and more than this, they are seen more clearly, but their number increases from one to six.

Oxalic acid dissolves the envelopes. the central vesicles from two to five in number remaining.

Tartaric acid quickly dissolves the envelopes; the central vesicles, observed of a white colour, remain.

Diluted nitric acid 1,170, corrugates the globules, and tinges them of a deeper yellow colour.

Diluted hydrochloric acid 1,070, corrugates the globules.

A dilute solution of the nitrate of silver 1,075, corrugates the coverings of the glo-

bules, and leaves them tinged of a yellowish colour.

Concentrated solution of nitrate of silver 1,275, at first dissolves the coverings and the primitive molecules, the central vesicles remaining, from one to four being seen clearly; but in a longer time the central vesicles themselves becomes dissolved.

Solution of pure potash, 1,350, dissolves the globules, and a white pellucid mucous fluid remains.

Spirit of caustic sal ammonia 0,980, produces no change.

Lime water occasions no change.

Spirits of wine 0.830, contracts the globules.

In crude pneumonic sputa, white, irregular, turbid particles are found intermixed with mucus, which are composed of an entire patch of cells of non-nucleated epithelium joined to each other in symmetrical order, on whose surface irregular globules (plastic exudation) are found.

Tenacious mucus of yellow globose sputa, which embrace or enclose the globules above described, appears, when submitted to the microscope, white, almost pellucid, and free from globules.

Distilled water does not produce any change in it.

Treated with nitric acid 1,170, it forms yellow filaments, decussating among themselves in different directions, and marked with irregular, obscure margins.

The same happens if it have been treated with hydrochloric acid, 1,070.

Solution of nitrate of silver 1,075, forms filaments, which after a little time are dissolved.

Concentrated acetic acid 1,030; solution of oxalic acid; solution of tartaric acid, occasion no change.

Of Sputa generated by Anomalous Inflammation, and from the Tubercular Process.—Sputa generated by the tubercular process differ according to the nature, the extent, and the stage of the disease.

The tubercular process is three-fold:—

1. Miliary tubercular process. 2. The tubercular process of infiltration. And, 3. The tubercular process, forming solitary tubercles, distinguishing by turns the characteristic sputa which each process forms.

Of sputa ejected from the process forming Solitary Tubercles.—A solitary tubercle, generating in the texture of the coats of the air-tubes, or in the cellular tissue surrounding the bronchi or blood-vessels, only affects the pulmonary secretion so as to increase it, and also presses upon the coats of the intermediate and capillary blood-vessels, as well as upon those of the minute bronchial ramifications, so much so as to impede or totally put a stop to the circulation of the blood, as well as air, in that small portion of lung

lying next the tubercle. The product generated from the irritation of the mucous membrane differs in no respect from that of a mucous membrane irritated by the application of cold, therefore there is as yet no *qualitative* difference between the sputa of an incipient catarrhal process, and those of a commencing tubercular process; but a *quantitative* difference is given, for the sputa ejected from an incipient catarrh are more copious than those which were expectorated from the irritation of a solitary tubercle.

The tubercle increasing, the quantity of sputa increases until the tubercle becomes softened, which, having taken place, besides the concocted or puriform sputa, there are found yellowish-white and finely granulated particles mixed with the white mucus; or, yellowish-white oval lenticular particles, whose longest diameter scarcely exceeds the half of a Viennese line, adhering to the bottom of the smooth vessel in which the sputa are accumulated.

It is seen by the microscope that these yellowish-white particles are a compound of roundish or ovate lenticular spheres, gashed globules, and mucus. The lenticular spheres are from the same size to ten times larger than the globules of pus; they present, for the most part, a smoothish surface, and, in almost all, obscure striae, running concentrically, are detected. Some of these spheres are fissured once or oftener from the periphery towards the centre, the broadest part of the fissure continually decreasing, until it altogether ceases far in towards the centre. They are easily broken, and break with angular margins; whereas, if one look closely at the face of the fracture, he will perceive the lenticular sphere to be composed of concentric lamellae, resembling a bulb of garlic.

The lenticular spheres fall to the bottom in distilled water. Dried for a long time in air, they are not changed, with the exception of a slight diminution of their diameter.

They are not changed by distilled water.

A solution of caustic potash dissolves them.

They are in no respect changed by liquid ammonia 0,910.

Concentrated acetic acid 1,030, and solutions of tartaric and oxalic acids, produce no change.

In dilute nitric acid all their diameters are enlarged from three to five times, and the concentric striae disappear; they swell like inflated bladders, become semi-transparent, are bent in a different manner, and ultimately disappear altogether.

They are not changed in hydrochloric acid 1,070.

Carbonate of soda, acetate of lead, prussiate of potash, and ammoniacal sulphate of copper, do not change them.

Solutions of the nitrate of silver 1,275,

change them in the same manner as nitric acid, only they do not disappear so quickly.

Infusion of galls, and pure alcohol 0,830, produce no change.

As long as the softened tubercle shall not have thoroughly been thrown off, so long are the lenticular spheres mixed with the sputa.

The tubercle being expectorated, the sputa again differ according to the difference of the pathological process; for, if the tubercular process has been local, the parietes of the cancer secrete globules of pus, which are ejected in union with the mucus of the irritated or inflamed mucous membrane of the air-passages, until the contracted parietes and the cavern, forming a cicatrix by granulation, become consolidated, the lenticular spheres being no longer detected in the sputa.

But if the tubercular process (the individual labouring from a tuberculous dyscrasia), is not quieted by the ejected tubercle, the lenticular spheres are found constantly intermixed with the sputa.

There are seen in the tuberculous sputa, besides the lenticular spheres now described, and white tenacious flocculi before noticed, white mucous and granular-looking shreds. Investigated by the microscope they contain cells* composed of tetra or pentagonal margins with obscure or unequally yellow centres, the striated margins having the diameter and texture of the intermediate vessels (capillaries.) Besides these cells, there are here and there found yellow cylindrical fibres marked with black transverse lines (muscular fibres.)—*Microscopic Journ.*

CASE OF

RUPTURE OF THE DIAPHRAGM.

THOUGH a constant reader of your valuable periodical *The Veterinarian*, I have not seen many cases recorded of death almost immediately following rupture of the diaphragm. I will therefore take the liberty of sending one, and if it is deemed worthy of insertion, it is at your service.

On the 8th of January last, Mr. Cope, whose pupil I have the honour to be, was desired to look at a black mare, the property of a farmer in this country, who said that, in coming up one of the steep hills that are so plentiful in this county, she stopped suddenly and breathed very laboriously, so that he could hear her at a great distance off. She was unable to proceed for full fifteen minutes, and then she slowly journeyed on with her load, which was upwards of a ton. On coming under our care the following symptoms were presented:—

* Infiltrated pulmonary cells, (cellulas pulmonales infiltratas.)

She was constantly lying down and getting up again—while down she would frequently turn her head to her side—she perspired very much—the pulse was 80, and hard—the extremities moderately warm.

Venesection was had recourse to immediately, and copiously; and opium, combined with ol. lini was administered; but in despite of all our efforts she died in about six hours after the first appearance of illness.

It would be useless to occupy much time in describing the post-mortem appearances: suffice it to say, that on examining the chest the diaphragm was found to be ruptured. The rupture extended about seven inches, and a large portion of the intestines had protruded through the opening. They were very considerably inflamed, and this rupture was doubtless the cause of death.—*Mr. Osborne, in Veterinarian.*

was opened; but the hæmorrhage was promptly arrested by tents steeped in a styptic liquid, and introduced into the wound made by the trocar.

The reporter concluded by proposing that Dr. Lecanus should be thanked for his interesting communication, and that his paper should be deposited in the archives of the Academy.

M. DUBOIS (of Amiens).—I should wish to know whether the author of the case has sought for, and mentioned, the causes of this ascites? Did he ascertain the state of the liver and spleen? In short, did he recognize any organic disease?

M. LONDE.—The author does not speak of any organic disease; he only mentions a chronic inflammation of the intestines and peritoneum.—*Gazette Médicale*, Sept. 24, 1842.

REMARKABLE CASE OF ASCITES.

EMPYEMA.

At the sitting of the French Academy of Medicine, on the 20th of September, M. Londe read, in his own name and M. Jobert's, a report on a case sent to the Academy by Dr. Lecanus, of Yvetot. It was an account of a woman who was tapped 866 times for ascites, of which she has been completely cured these two years.

The interest of this case, said the reporter, consists in the knowledge of all the details which I am about to analyse.

A woman, aged 36, was attacked, in 1823, by a chronic entero-mesenteritis, accompanied by marasmus, suppression of urine, and irregular menstruation. By degrees the abdomen became of enormous size, from the presence of fluid accumulated in the cavity of the peritoneum. The first tapping gave issue to twenty pounds of a lemon-coloured limpid fluid; and M. Lecanus ascertained, after the sinking of the abdomen, that it contained enormous indurations. Ten days afterwards she was again tapped, and so rapidly did the fluid accumulate, that it was necessary to repeat the operation every six, eight, ten, or at the utmost twelve, days. Fifteen years had elapsed in this manner, and tapping had been performed 810 times, when Dr. Lecanus thought of trying compression on the abdomen with pieces of paste-board covered with linen. This remedy, employed gradually, at first retarded the accumulation of the fluid; and at the end of six months, during which tapping was practised at more or less distant intervals, it was perceived that the ascites no longer returned. The patient has now been completely cured these two years, having undergone tapping 866 times during 15 or 16 years. Once only the epigastric artery

At the meeting of the Academy of Sciences, on the 19th of September, a memoir was read by M. Faure, first Physician to the Military Hospital at Toulon, on paracentesis of the thorax, performed for the cure of pleuritic effusion.

In this paper M. Faure begins by showing the importance of the subject of empyema, and he refers to the discussions which took place in the Academy of Medicine on occasion of a memoir upon the same subject which he addressed to that learned society.

The author shows, that in pleuritic effusion, paracentesis of the thorax is, in the majority of cases, the only means of endeavouring to save the patient from an almost inevitable death; and that this operation is far too much neglected because, he says, its dangers have been exaggerated; while, on the other hand, its indications have not been well appreciated, nor the time precisely pointed out when we ought to have recourse to it.

M. Faure lays it down as a principle, that by puncturing the thorax with a trocar, we are safe from a very dangerous accident, the entrance, namely, of air into the thorax; and affirms that at the expiration of forty-eight hours, there frequently remains no trace of the puncture. Lastly, after having said that more than 200 persons die annually, suffering under thoracic effusion, whose life might have been prolonged, or their last moments rendered less painful by paracentesis, M. Faure cites three cases of empyema for which he operated at Toulon, last April and May. The patients, who were all soldiers from Africa, were in great danger from pleuritic effusion, suffocation being imminent. One died a few days after the operation; the other two were still alive on the 31st of July,

when M. Faure received accounts of the sequel of these three operations.

MM. Magendie, Serres, and Breschet, were commissioned to report on this memoir.—*Gazette Médicale*, Sept. 24th, 1842.

CUBEbine.

M. MONHEIM has described, under the above term, a volatile substance. M. Cassola, under the same name, has described a soft and resinous, and Messrs. Soubeiran and Capitaine a crystallized substance. M. Steer has confirmed the result of these latter writers by renewed experiments, the result of which we proceed to relate. After having submitted the cubeb pepper to distillation, in order to remove the essential oil, it is dried, and an alcoholic extract is made, which is distilled until there remains only one-fourth of the primitive volume, and which is then filtered, previous to submitting to renewed distillation. When this has been done, a residue containing some resin is obtained, and which assumes the condition of a mass approaching to the crystalline form, when allowed to remain in a cold place. This crystalline mass is placed on linen, which allows the resinous liquid to percolate (the cubebine of M. Cassola): after twenty-four hours this is almost completely removed, and the mass which remains is dissolved in three or four times its weight of boiling alcohol, sp. gr. 0.90. The solution is allowed to clarify, maintaining the boiling temperature, the liquid is decanted from the undissolved resin, and the cubebine crystallizes on cooling. In order to purify it, it is dissolved in concentrated boiling alcohol; animal charcoal, and a little boiling water, are afterwards added: the boiling liquid is filtered, and then allowed to cool, by which the cubebine is precipitated in needles of some lines in length, uncoloured, and of a pearly lustre. It crystallizes from concentrated alcohol in grains. Under this form it possesses but a weak odour of cubebs, and is insipid, although the spirituous solution has a bitter taste. It is insoluble in water, almost insoluble in cold alcohol, but very much so in boiling alcohol, even when it contains some water. It separates from the solution on cooling under the form of flakes, and these are readily soluble in cold alcohol.—*Annals of Chymistry and Pract. Pharmacy*, No. I.

ROYAL COLLEGE OF SURGEONS.

LIST OF GENTLEMEN ADMITTED MEMBERS.

Friday, October 7, 1842.

R. D. Adams.—W. Thomas.—J. Conan.—W. G. Walker.—H. S. J. Clarke.—G. Stockil.—J. Christie.—G. H. Mansdorp.—A. G. Purchas.—J. Kenyon.—H. Graves.—W. C. Thurgar.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, September 29, 1842.

W. W. Hyde, Witney, Oxon.—A. G. Purchas, Pilstone, Chepstow.—F. A. Tipple.

October 6, 1842.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE III.

*The Anatomy of the unimpregnated Uterus
and its appendages.*

THE ovaria and fallopian tubes, the uterus, vagina, and external organs, compose the generative system of the human female. The uterus is situated within the pelvis, behind the bladder, before the rectum, below the small intestines, and above the vagina. The vagina extends downwards and forwards obliquely between the bladder, urethra, and rectum, from the uterus to the vulva, which is situated at the outlet of the pelvis. Between the layers of peritoneum, which are reflected from the sides of the uterus to the pelvis, forming the broad ligaments, are inclosed the fallopian tubes, ovaria, and round ligaments.

The two ovaria are situated on the sides of the uterus, in the posterior duplicatures of the broad ligaments, behind and a little below the fallopian tubes. At the age of puberty the ovaria are of an oblong form, flattened on the anterior and posterior surfaces, varying from an inch to an inch and a half in length, and from a quarter to half an inch in thickness. The inner extremity of each ovarium is fixed to the uterus by a short band or ligament, chiefly consisting of fibres sent off from the muscular coat of the uterus. In this preparation there is a small fibro-cartilaginous tumor, with its blood-vessels injected, which has been formed in the right ovarian ligament. The outer ex-

tremity of each ovarium is always attached to the corpus fimbriatum, and by this means the relative situation of the ovarium to the fallopian tubes and uterus is preserved.

The ovaria consist of a serous coat derived from the peritoneum, and a dense parenchymatous structure, called the stroma, in which the Graafian vesicles or ovisacs are contained. Some anatomists describe a fibrous tissue under the peritoneum of the ovary, which they have called the tunica albuginea. The Graafian vesicles differ from one another in size. On an average they measure about two lines in diameter, and generally exceed ten in number. The largest project at the surface, and the smaller vesicles are imbedded in the stroma of the ovary. Each vesicle consists of two distinct coats or membranous layers, which adhere so firmly, that they are separated with great difficulty from one another. Their outer coat adheres loosely to the stroma of the ovary by soft cellular membrane, through which numerous arteries and veins pass to the vesicle, and ramify upon its coats. The frequent extravasation of blood into the cavities of the Graafian vesicles proves that their inner membrane is vascular.

Within each Graafian vesicle is a layer composed of granules; and within this layer is contained an albuminous fluid. Imbedded in that part of the granular layer corresponding to the place where the wall of the Graafian vesicle is in contact with the peritoneum, is the ovum or ovule. This is a very minute body, of a rounded form, consisting of yelk granules contained within a thick transparent envelope, which is just perceptible to the naked eye. The part of the granular layer where the ovum is situated is in the form of a disc, in which there is a cup-like depression, in which the ovum lies. The disc is called the proligerous disc. If a Graafian vesicle be removed from a recent human ovarium, and opened upon a plate of glass, and the contents pressed out, the transparent ovum can

readily be observed with the naked eye, or with a simple magnifier, after the opaque granules in which it is imbedded have been washed away with a few drops of pure water.

According to the independent microscopical observations of Coste in the rabbit, and of Valentin and Mr. Wharton Jones in several of the mammifera, there is a transparent vesicle, about one-sixth of the diameter of the ovum, inclosed within it, which is analogous to the vesicle which exists in the cicatricula of the immature eggs of birds, and also in the ova of all other animals. This is called the germinal vesicle; and on one side of this there is an opaque spot, called the germinal spot.

This spot was discovered and described simultaneously and independently in this country and in Germany by Mr. W. Jones and Professor Wagner. The germinal vesicle, and the spot on its side of the mammiferous ovum, was, I believe, first shewn in London in 1837, at the College of Surgeons, by Mr. Wharton Jones, two years after I had presented his paper to the Royal Society describing and delineating it.

The earlier anatomists believed that the ovaria performed a function similar to the testes. Harvey supposed something indefinite came from the ovaria, but thought it was only in the uterus that the ovum was formed. Steno having observed the Graafian vesicles in the ovaria of the deer, guinea-pig, sow, ass, wolf, &c., and supposing them to be ova, concluded that the ovum is first formed in the ovaria, and afterwards developed in the uterus.

De Graaf, in 1672, first accurately described the structure of the ovaria, and the vesicles they contain. He ascertained that these burst after impregnation; that a yellow substance, called the corpus luteum, is formed in the situation of the ruptured vesicles; and that the number of these yellow bodies corresponds with the number of embryos subsequently found within the uterus. In the fallopian tube of the rabbit, three days after impregnation, he saw bodies of a defined shape, much smaller in size than the vesicles in the ovaria, from which, recognising these bodies as ova, he inferred that these vesicles of the ovaries are not the ova. In 1778 Cruickshanks made some experiments, which confirmed the accuracy of De Graaf's observations, which had been called in question by Haller and other physiologists. Prevost and Dumas twice perceived a small spherical body within the unimpregnated Graafian vesicle of the rabbit, which they suspected was the ovule. Professor Baer first unequivocally demonstrated, in 1827, the ovum in the ovary; but he mistook its nature, supposing it to be analogous to the germinal vesicle discovered by Purkinje two years before, in the cicatricula of

the immature egg of the bird. The discovery of the germinal vesicle in the mammiferous ovum by Coste, Valentin, and Jones, demonstrated the inaccuracy of Baer's view, and established the true nature of the body contained in the Graafian vesicle.

The ovaria are long and slender in the fœtus, and are then placed upon the psoæ muscles, a little way under the kidneys. They contain small Graafian vesicles soon after birth. At the age of puberty their volume increases, and the Graafian vesicles enlarge and contain ova. The surface of the ovaria is perfectly smooth [exhibiting a preparation] until the period when menstruation commences: it is afterwards marked by irregular depressions, like cicatrices, in the peritoneal coat. After the cessation of this function the ovaria shrink, become hard and *unequal*, and the coats of the Graafian vesicles are thick and opaque, and their cavities often filled with a black, red, or fawn-coloured substance, of a soft consistence. In extreme old age the parenchymatous substance of the ovaria is so much diminished, that they are not larger than those of a young child, and have the same shape.

The development of the pelvis, uterine system, and mammae, the function of menstruation, and all the peculiarities of the human female, depend upon the ovaria. The ovaria may be considered as the essential organs of the generative system in all the different classes of animals, for they are always present, whatever form this system may assume. At each menstrual period a Graafian vesicle bursts, and the contents escape. When the ovum is impregnated, it passes from the ovary into the fallopian tube, and a corpus luteum is formed around the Graafian vesicle in which it had been contained.

The ovaria are liable to many diseases from the age of puberty to the period when the catamenia disappear. Their peritoneal coat often becomes inflamed, and false membranes are formed, by which they become firmly united to the fallopian tubes and uterus. The coats of the Graafian vesicles are often in a thickened morbid state, and their cavities distended with blood and other fluids. Great cysts and tumors, some of which are of a malignant nature, are not unfrequently formed in the Graafian vesicles, or parenchyma of the ovaria. All these, and the diseases of the unimpregnated uterus, fallopian tubes, vagina, and external parts, which are numerous and important, will be considered in a subsequent part of the course.

The *fallopian tubes* extend between the upper and lateral parts of the uterus to the ovaria. They are from four to five inches in length, and are situated in the middle duplicatures of the broad ligaments, between

the two layers of peritoneum ; as the intestines are in the mesentery. They pass from the sides of the uterus at first upwards and outwards, and then downwards, where each terminates in a wide, open, expanded extremity, which is divided into fringes, and is called the corpus fimbriatum. In each fallopian tube there is a canal, by which a communication is formed between the peritoneal cavity and the cavity of the uterus. This canal is very slender, where it is entering the uterus, being only sufficient to admit a bristle, but it is wider toward the outer extremity. Air and mercury pass readily along the tubes, from the corpora fimbriata into the cavity of the uterus.

The fallopian tubes consist of a peritoneal, muscular, and mucous coat. The latter is a continuation of the mucous membrane which lines the cavity of the uterus ; and through the whole course of the tube, it forms longitudinal plicæ, which run in a spiral direction, as in the oviducts of birds.

Between the mucous and peritoneal coats of the tube is situated the muscular coat. In the ordinary condition of the tube, the fibres of this coat are so thin and pale, that it is difficult to demonstrate them, and some anatomists have, in consequence, expressed doubts about the existence of a muscular coat in the fallopian tubes.

Here is a specimen of fallopian tube gestation, [exhibiting it] in which the muscular coat of the right fallopian tube is more than a quarter of an inch in thickness. The entire ovum is contained in the tube about midway between the two extremities ; the decidua, chorion, amnion, placenta, embryo, and even the vesicula umbilicalis, are all in the tube, and there is no vestige of decidua within the uterus. The walls of the tube had performed in this case all the functions of the uterus, till the time it burst, and the fatal internal hæmorrhage took place. The muscular coat of the tube could readily be separated into distinct strata or layers, like the walls of the gravid uterus, and you can see large veins running through it similar to the sinuses of the uterus. I traced a communication by means of the coagula of the fibrine of the blood which filled these veins, between the interstices of the foetal vessels of the placenta, and these veins in the muscular coat of the tube, which opened obliquely into one another, and enlarged as they proceeded outward to the surface, where they terminated in one of the spermatic veins.

One of the best modes of examining the structure and connexions of the fallopian tubes is to remove them with the ovaria from the uterus, and lay open the canal of the tubes from the corpora fimbriata to the uterus, and cover them with water or alcohol, or suspend them in fluid. This

has been done in another preparation I now show you, and the tube thus opened, the walls of the canal of which are held asunder with bristles, is suspended by the ovarium in alcohol.

A bristle fills the canal where it is cut across near the uterus. The canal is seen enlarging towards the corpus fimbriatum, and the longitudinal folds of the lining membrane are remarkably distinct. The corpus fimbriatum presents the appearance of a large soft vascular membrane, folded up like a fan or umbrella, and one of its broad fringes is seen uniting with the outer extremity of the ovary. The peritoneal coat of the ovary is continuous with that of the fringe, by which the tube and ovarium are united.

In another preparation, [exhibiting it] the blood-vessels of the ovaria and fallopian tubes have been very successfully injected. Numerous branches of arteries from the spermatics are seen proceeding to the tubes, and especially to its outer extremity, and forming complete loops or rings around them. Branches from the same arteries supply the ovaria. There is a plexus of great tortuous veins also seen extending between the base of the ovaria and the tubes, which are much larger than they would be if their sole function were to return the blood from the arteries of the tube. These veins probably answer the purpose of an erectile tissue, and cause the necessary approximation of the ovaria and tubes when conception takes place.

The structure of the fallopian tubes is often destroyed by adhesive and suppurative inflammation. An accumulation of a large quantity of fluid sometimes takes place in their canals, when their extremities have been closed by inflammation and other causes. In persons who have died of tuberculous phthisis, I have occasionally seen a quantity of soft scrofulous matter within them, and their coats thickened and indurated. Fibrous and malignant tumors are very rarely developed in the walls of the fallopian tubes.

Ciliary movements have been observed by Purkinje and Valentin in the mucous membrane of the fallopian tubes, uterus, and vagina of the rabbit, both before and after impregnation. The direction of the motion is from within outwards. I do not know whether this has been seen in the human subject.

In shape the uterus resembles a pear, about three inches long, compressed before and behind. The large extremity is placed superiorly, and the smaller inferiorly in the pelvis. The uterus is in the direction of the brim of the pelvis, and the vagina, with which it forms a great angle, is in the axis of the outlet. The uterus is divided into fundus, body, cervix, and orifice. The

fundus is the convex portion which lies above the entrance of the fallopian tubes into the cavity. The *body* of the uterus extends between the fundus and *cervix*, which is the contracted part below, and which terminates in the *os tinea*. The uterus consists of a dense muscular coat, which is invested on the outer surface by peritoneum, and internally by a mucous membrane, which is continuous with the inner membrane of the vagina and fallopian tubes. The peritoneum adheres firmly to the muscular coat of the whole fundus, and a considerable portion of the body of the uterus; but between the muscular coats and peritoneum of the lower part of the body and cervix there is a quantity of soft cellular membrane interposed. The peritoneum behind passes down, and, after covering the whole cervix uteri and a small portion of the vagina, is reflected upward over the rectum. The anterior part of the cervix uteri, being in immediate contact with the bladder, is not covered with peritoneum. The muscular coat is so dense that it is impossible to separate and to trace the particular direction of the fibres of which it is composed, or to demonstrate the course which they pursue, as we can do in the gravid uterus. Around the fallopian tubes they appear to run in a concentric direction. From the upper and forepart of the uterus, near the fallopian tubes, the round ligaments pass off, which run through the abdominal canals, and are lost about the groins and external parts. These have an entirely different structure from the broad ligaments, which are layers of peritoneum, or from ligaments in any other part of the body. In the gravid uterus it can be readily shewn that they are almost entirely composed of fibres sent off from the muscular coat of the uterus with blood-vessels and nerves.

If an incision be made through the walls of the uterus before or behind, its small triangular-shaped cavity, lined with a vascular membrane, comes into view. The fallopian tubes open into its upper angles, and the cervix uteri into its lower.

The *cervix uteri*, which varies in length, is contracted at the upper and lower, or uterine and vaginal orifices. The *penniform rugæ* are situated in the middle part of the cervix, between which there are seen numerous orifices of compound mucous ducts or lacunæ, which secrete a peculiarly viscid matter. The Nabothian glands, which often present the appearance of small sacs distended with viscid fluid, are situated both upon the margin of the os uteri and within the cervix. The *os uteri* has two lips, with a transverse chink or depression, which is sometimes so slight that it can scarcely be felt with the point of the finger. There is a great difference observed in the length of

the cervix, in the shape of the orifice, and condition of the lips, in different subjects. In some the os uteri is like a flattened nipple, and projects slightly into the vagina; in others it is round and prominent. The anterior lip usually hangs lower in the vagina than the posterior: the vagina being united to the cervix uteri higher up than before. In women who have had children the os uteri is not so uniformly smooth and regular as in those who have never been confined.

The internal membrane of the uterus is so thin and delicate, and adheres so firmly to the muscular coat, that its existence, as a separate tunic, has been called in question by some anatomists. In several preparations [exhibiting them] fibrous tumors have been developed under this membrane; and you can see it distinctly reflected over the surface of these tumors from the uterus. The appearances presented by the fibres of the middle coat of the gravid uterus, and the sensibility and contractile power of the uterus during labour, prove, beyond all doubt, that it is muscular, which has likewise been disputed.

The vagina extends from the uterus to the external parts. It consists of an internal mucous membrane, and of a dense highly elastic fibrous tissue, in which numerous arteries and veins ramify, and to which many nerves are distributed. The coats of the vagina are continuous with the middle and internal coats of the cervix uteri. This is clearly seen in a preparation [shewing it] of the uterus and vagina, in which the cervix is much elongated, and the coats of the vagina thickened from irreducible prolapsus for several years. The penniform rugæ and compound lacunæ are also much more distinctly seen in this lengthened cervix than in the ordinary condition of the part. Near the orifice of the vagina the lining membrane, especially of the anterior wall, is thick, and deep transverse rugæ or plaits are observed in it, and in the posterior surface. There are numerous papillæ on the edges of these rugæ, and many mucous follicles between them. The vagina is widest at the upper part, where it is attached to the uterus; and its lining membrane is more smooth than near the orifice.

There is a great plexus of veins in the outer coat of the vagina near its orifice, which is also surrounded with the sphincter vaginæ muscle. The vagina adheres firmly by cellular membrane to the urethra, the bladder, and rectum. Its upper extremity is attached to the neck of the uterus lower down before than behind. The posterior wall of the vagina is separated from the rectum the whole thickness of the perineum, by a triangular space, which is filled with a cellular membrane. The direction of the axis of the

vagina, as I have already said, does not correspond with that of the brim, but of the cavity and outlet of the pelvis.

The orifice of the vagina is about an inch and a half from the symphysis pubis; and it is either partially closed by the *hymen*, which is a doubling of the lining membrane, of a concentric shape, or it has several small prolongations of the lining membrane projecting from it, which are called the *carunculae myrtiformes*.

The *mons veneris*, labia, clitoris, nymphæ, vestibulum, and perineum, are the external parts of generation. The *mons veneris* is situated over the symphysis pubis, and is composed of adipose and cellular membrane covered by the integuments. It divides into the *labia*, which pass down and bound the orifice of the vagina on each side, and afterwards unite at the anterior border of the perineum.

Between the labia is situated the *vulva*, which contains the clitoris, nymphæ, and the orifices of the vagina and urethra. The body of the clitoris, which is situated at the upper part of the vulva, is formed by the union of its two crura, and its anterior extremity is covered by the prepuce, from each side of which one of the nymphæ descends obliquely about an inch and a half. The nymphæ chiefly consist of dense cellular tissue and blood-vessels. Under the clitoris and between the nymphæ is the smooth triangular space called the vestibulum, at the lower part of which, and immediately above the ostium vagina, is the orifice of the urethra. The urethra passes to the bladder under the symphysis pubis along the upper surface of the vagina, to which it is firmly united by a thick fibrous and vascular structure. The mucous membrane of the urethra is usually of a red colour, and it is perforated with the ducts of several mucous glands. Two of these, near the orifice, have been called Cowper's glands of the female. The perineum extends from the posterior commissure of the labia or fourchette to the anus. Within the fourchette is a smooth depressed cavity called the fossa navicularis.

The uterus and its appendages are supplied with blood from the spermatic and hypogastric arteries. The spermatics, after sending branches to the tubes and ovaria, pass down to the uterus, and there freely anastomose with the uterine branches of the hypogastrics. The upper part of the uterus is chiefly supplied with blood by the spermatic arteries; and the body, cervix, and vagina, solely by the hypogastrics. The whole muscular coat of the uterus, as you may observe in this preparation, is pervaded with innumerable convoluted branches of the spermatic and hypogastric arteries, which have been injected, and are seen passing obliquely through the different strata to the

lining membrane. The veins form a great plexus in the muscular coat, which can readily be traced from the inner to the outer surface of the uterus, opening obliquely into one another, and enlarging as they approach the trunks of the spermatic and hypogastric veins. Even in the unimpregnated uterus the veins form great plexuses, not only in the substance of the organ, but around the cervix and body, and in the walls of the vagina, and between the ovaria and fallopian tubes. In this preparation [exhibiting it] all these veins have been filled with blue injection; and so large are they, that the uterus appears literally imbedded in them. At the full period of pregnancy the veins in the substance of the uterus form one of the greatest plexuses in the human body; and where the placenta adheres, they open, after its separation, into the cavity of the uterus. The lining membrane of these great veins—and they have only one membrane, and no proper valves—is continuous with the mucous membrane of the uterus, as the lining membrane of the fallopian tubes is continuous with it and with the peritoneal sac. I believe it is in consequence of the peculiar manner in which the great veins open into the cavity of the uterus that attacks of uterine and crural phlebitis occur so often after delivery, and of which I now show you one of the most striking examples that has yet been observed.

Upon the table is the uterus, and all the veins connected with it, of a woman who died on Monday, the 9th instant, four weeks after delivery, and who had true phlegmasia dolens in both lower extremities, the left having been first and most severely affected. She was under the care of Mr. Brookes, of Bedford Street, and Mr. Jones, Soho Square, and suffered chiefly from great debility, fever, constant sickness, and diarrhoea. I examined the body with Mr. Beck on the 12th instant (the day before yesterday); and we removed all the pelvic viscera, blood-vessels, and nerves, which you now see. There is no trace of peritoneal inflammation about the uterus; and the intestines were perfectly sound. All the veins of the cervix uteri, on the left side, are filled with pus and lymph, and coated with false membranes. The same is the condition of the left internal, common, and external iliac and femoral veins. The coats of the vena cava are greatly thickened as high as the diaphragm, and a rough false membrane adheres to the whole of its inner surface. Within this is a soft yellowish substance, which washes away like a mixture of pus and lymph, with coagula of blood. A quantity of purulent fluid escaped from the vena cava when it was opened near its bifurcation; and at this point there was a firm union between the vein and the last lumbar

vertebra and cartilages. The right common, external, and internal iliac, and femoral and saphena veins, are all destroyed by inflammation, though less disorganized than on the left side. The left spermatic vein, from the uterus to its termination in the renal vein, is thickened and lined with false membranes, and filled with coagula of blood. The liver and lungs contained no secondary abscesses. An incision was made through the integuments and cellular tissue down to the fascia of the right leg, which was most swollen, and a quantity of serum flowed out of the cellular tissue, which appeared quite healthy.

This dissection demonstrates that in this case of phlegmasia dolens the inflammation commenced in the uterine branches of the hypogastric veins, and subsequently extends from them into the iliac and femoral trunks of the affected side.

The absorbents of the uterus and its appendages accompany the spermatic and hypogastric veins. As they are extremely small, and are demonstrated with great difficulty in the unimpregnated uterus, and as I have no preparation to shew them injected, nor have ever seen one, it will be more satisfactory to describe them hereafter with the nerves of the gravid uterus.

CLINICAL NOTES,

By J. ADAIR LAURIE, M.D.

Professor of Surgery, Anderson's University,
Glasgow.

I. ON SOME OF THE MORE UNUSUAL FORMS OF ANEURISM.

Cricoid aneurism of right arm—Operation —Cure.

MURDOCH M'LENNAN, æt. 21, bleacher.

All of the arteries of the right upper limb, especially the larger arterial trunks, are enlarged. The subclavian as high as it can be traced, the axillary, and the brachial, are fuller, larger, and of a much more powerful beat, than natural, — the latter vessel being apparently equal in size to the common iliacs. The pulsation is peculiarly vibratory. The radial artery is greatly increased in size, and tortuous throughout its course. About the middle of the forearm it bulges into a swelling about the size of the point of the thumb, which pulsates more strongly than any other part of the vessel, from the subclavian downwards, with a strong whirling vibratory feel, and a loud rasping soufflet. Its pulsations are distinctly visible, and resemble the action of a small energetic heart. On the same vessel, half an inch from the wrist, is another swelling, as large as a pullet's egg, of an ovoid form, with a somewhat promi-

nent apex. It pulsates throughout, has a loud rasping soufflet synchronous with the pulsation of the radial, from which vessel the tumor cannot be separated. It can be partially emptied by firm pressure on the artery above, or on its apex, and when so emptied its sides have a solid cartilaginous feel, the apex remaining soft. The integument is not discoloured. From this point the radial can be traced in its ordinary course on the back of the thumb, enlarged, tortuous, and presenting characters in other respects similar to those of the brachial. The ulnar artery, in like manner, can be traced in the lower half of the forearm, presenting pathological appearances precisely similar, until it arrives opposite the larger tumor on the radial. It there seems to attain a greater degree of dilatation and tortuosity, extending across the wrist, forming a flattened swelling as thick as the finger, and as large as a half-crown piece, pulsating very violently, and communicating to the ear a loud rasping soufflet. The same swelling, more flattened, and pulsating with less violence, extends along the ulnar half of the palm, and seems to terminate in the slough afterwards to be described. The radial half of the palm, and the backs of the fingers, have the same appearance to the eye as that of the ulnar, but to the touch are devoid of pulsation, with a peculiarly soft semifluctuating feel as if occupied by a congeries of tortuous dilated veins. The integuments are hardly perceptibly discoloured, of a very slight blue tinge, with the exception of three red vascular spots, apparently superficial nævi; one on the palmar wrist, one on the palm, and one on the second finger. Pressure on the radial artery easily commands all pulsation in the course of that vessel, while that in the ulnar continues, and *vice versa*; while moderate pressure on any part of the artery above the bend of the elbow commands all pulsation in the forearm. Pressure on the arteries causes acute pain in the fingers and palm of the hand. Remaining portions of palm of hand, and roots of first and second fingers, are covered by clotted dressings, on partially removing which a foul sloughy surface is exposed. The third joints of the first and second fingers are bent at a very acute angle, beyond which they cannot be extended. The fingers themselves are soft, puffy, with a feeling of superficial fluctuation, painful but not pulsating. The thumb, ring, and little fingers, nearly normal. The veins of the arm are enlarged, and on admission were reported to pulsate feebly. The limb is smaller than its fellow.

Says that the pulsating swellings on the hand and forearm are congenital, and that they have not materially increased beyond the proportional growth of the limbs. The

lower tumor over the radial artery was about the size of a hazel-nut till six years ago, when it was suddenly increased in consequence of a blow, and has since gradually but slowly enlarged. Since childhood has been liable to suppuration and hæmorrhage from the palm, the latter occurring every 3d or 4th month, and easily checked by pressure. Within the last four years the discharge of pus has been constant, and the loss of blood more frequent and profuse. Five days ago the bleeding became unusually profuse, and before it could be checked by pressure, he lost two pounds of blood. Eight hours ago it returned, and he lost about an equal quantity. A tourniquet was then applied, and he was conveyed to the hospital.

On admission he was faint, and the pulse feeble. After he had rallied it was 116, soft. Action of heart strong; sounds are loud and regular. No soufflet detected in any other artery of the body, all of which, so far as can be ascertained, seem of a normal size. The tourniquet was taken off, and he was carefully watched.

March 12th.—By advice of consultation brachial artery was tied in lower third of arm. The vessel was exposed by a very careful dissection, the ligatures passed cautiously round it, and tied in the ordinary way. The artery was as large as the little finger, and its coats very thin. Pulsation in all the parts distal to the ligature immediately ceased. Did not lose two drachms of blood, and bore operation well. Wound dressed on table with strips of adhesive plaster.

13th.—Soon after operation complained of pain in palm of hand; relieved by morphia. Heat of limb quite natural, except fingers, which, however, are very little colder than they should be.

15th.—Points of two first fingers and thumb somewhat livid; veins on back of forearm and hand have the appearance of livid streaks, in which the circulation is going on slowly. A large arterial branch is felt beating on back of arm, and reaches nearly as low as the elbow. Action of the heart much excited, with severe palpitations and slight bellows murmur, most probably owing to reaction following the loss of blood previous to admission. Bowels slow.

R. Tr. Opii, Tr. Digitalis, Sp. Ammon. Aromat. aa. ʒj. Tr. Hyosciam. Nigr., Vini Antim. ʒij. Aq. Cinnam. ʒv. Sum. ʒj. ter indies.

22d.—The palpitations ceased, the appearances of gangrene on the fingers and thumb did not extend, and he continued doing well till the 20th, at 4 P.M. when profuse hæmorrhage recurred from situation of

former bleedings. The house surgeon, and the young men who were assisting him, reported that pressure on the subclavian and brachial had no influence in restraining the flow of blood, which could only be arrested by firm pressure on the bleeding point. Pulsation having returned to the ulnar artery, it was proposed to tie that vessel immediately; but to this the patient would not submit until to-day. The vessel was tied an inch and a half above the wrist, and was found large and very tortuous. Did not lose a tea-spoonful of blood. Compress and bandage were continued to palm of hand.

24th.—First and second fingers sphacelated; point of thumb gangrenous. A livid patch over first phalanx of little finger. Wound of first operation dressed for first time to-day. Ligature came away in the dressings; wound looking well.

28th.—Wound of operation on ulna dressed to-day, and looking well. Ligature came away. First and second fingers dead as low as articulations with metacarpal bone. Other parts of hand as formerly. The apex of the larger tumor on radial discoloured.

May 18th.—Since last report has gone on favourably. The first and second fingers have been removed, and the wound is granulating healthily. The gangrene of the thumb did not extend beyond its point, which has not yet separated. One or two of the articulations of the ring and little fingers were opened by the separation of the sloughs, the projecting ends of the bones were snipped off with bone forceps, and the parts are now looking well. The apex of the tumor mentioned in last report sloughed, and several large portions of calcareous deposit were discharged from it, confirming the opinion given of it in the original statement of the case.

General health very good; walks out daily.—Dismissed cured.

September 18.—This young man called upon me to-day. Sloughs have separated from fingers and thumb, and the sores have nearly healed. Can now move thumb and little finger, but not ring finger. Sore left by removal of two first fingers has not yet healed, but presents an indolent ulcer about half an inch broad by an inch long. Palm of hand fully more soft and flaccid than when he left the hospital, and pulsating obscurely. No pulsation to be felt in any part of ulna; radial artery pulsates feebly throughout; smaller swelling on this artery about middle of forearm still exists, but smaller, and pulsating mildly; ulcer left by breaking up of larger swelling has cicatrised; anterior inter-osseous is felt very obscurely, if at all. Brachial at bend of arm is enlarged, but does not beat strongly; it is obliterated for an inch at the point where it was tied, a branch

is found to beat in its immediate neighbourhood, and the vessel formerly noticed on the outside of the arm continues still of considerable size. The axillary and subclavian arteries are as large as they were on admission into hospital. The latter of these vessels has an approach to a double sound, heard most distinctly when the patient is in the erect posture; when sitting, the second sound has none of the bellows murmur. The heart, carefully examined, was healthy.

This case, of confessedly a rare disease, more particularly in the extremities, appears to me worthy of being recorded. So far as I am aware, examples occurring in the extremities were first published by Breschet, in his excellent memoir on Aneurisms, in the 3d vol. of "*Mémoires de l'Académie Royale*," for 1833. His first case (p. 138) is, in many respects, a complete counterpart of M'Lennan's. It was in the right arm, and the increased diameter of the brachials, with the tortuosity of the vessels of the forearm and hand, so much resemble M'Lennan's, that Breschet's first plate gives a very accurate representation of the state of the arteries in M'Lennan. It differed from it in this, that there was no hæmorrhage, no necessity for operation, and that the existence of the disease was only ascertained on dissection. Breschet's second case (p. 140) was on the right thigh and leg. The femoral artery was tied; partial gangrene, suppuration, and death, followed. Allusion is made to a third case, in which the iliac arteries were found dilated and tortuous, by Cloquet in 1816. In a fourth case, the disease existed in the inferior extremity; frequent hæmorrhage from an ulcer required interference; ligature of the femoral was deemed improper; amputation was performed, and the patient died (p. 183).

So far, then, as these cases go, they offered very little encouragement for the performance of an operation. In M'Lennan's case surgical interference was absolutely necessary in order to prolong his life. At a consultation several measures were canvassed, but I decided on tying the brachial above the elbow, as offering the greatest number of advantages. The success was, perhaps, greater than I had any reason to anticipate, for although the disease cannot be said to be cured, its progress has been arrested, the lad's life placed beyond immediate danger, and his limb preserved. So far as one case goes, it establishes the propriety and safety of tying arteries in similar cases, and it shows that there is no necessity for going so far from the disease as to enable us to tie a sound part of the vessel. At both the points operated on the vessels were highly diseased, and, in as far as the operations themselves went, they terminated as favourably as if the arteries had been healthy.

This case throws some light on the origin and nature of this curious arterial disease. It appears to me to go far, in conjunction with some other cases, to prove that it belongs to the same class of disease with nævus, and aneurism by anastomosis. In this case it was congenital, and presented on one limb examples of all the forms of the disease. On the integuments of the wrist, palm of the hand, and fingers, we had the simple nævus, consisting of a varicose state of the vascular tissue of the skin. At the roots of the first and second fingers, we had the erectile tissue ulcerated and bleeding most profusely. On the ulnar side of the palm of the hand we had tortuous enlargement, the vessel pulsating violently; on the radial side, we had apparently the same state of parts, but without pulsation; on the vessels of the forearm we had cricoid aneurism with thinning of the coats, tortuosity, and small aneurismal tumors of the mixed kind; and in the brachial, axillary, and subclavian, enlargement of the calibre of the arteries with thinning of their coats, but without tortuosity or aneurismal tumors.

Although these diseases are very probably essentially the same, and arise from the same cause, in a practical point of view it is important to recollect that they occur separately. It is farther of importance to divide them into cricoid aneurism without erectile tissue, and cricoid aneurism with the addition of erectile tissue. The prognosis of these two is different both before and after operations. *Before* operation the two diseases, when combined (and in many instances erectile tissue without cricoid aneurism) are liable to ulcerate, and endanger or destroy the patient by hæmorrhage. Cricoid aneurism without erectile tissue seldom causes hæmorrhage. *After* operation, when the only admissible operation is that of tying the arterial trunk supplying the disease, if the diseases are combined the utmost we can hope for is an arrest of their progress, not a radical cure. Numerous cases prove that, after ligature of the principal artery, cricoid aneurism combined with erectile tissue returns, and may end fatally, whereas ligature of the main artery, or even of the enlarged branches, will probably be found a radical cure for cricoid aneurism alone. I say "probably," not being yet in possession of a sufficient number of cases to prove it.

The *treatment* of the two cases must be different; when in combination it must consist of ligature of the main artery, followed *immediately* by local measures directed against the erectile tissue. M'Lennan's case, with many others, prove the necessity of this combination. In eight days after ligature of the brachial artery hæmorrhage returned, and was only arrested by ligature of the ulna, and local pressure; and notwithstanding

these measures were aided by partial sphacelus, inflammation and its attendant condensation of the surrounding tissues, the disease cannot be said to be radically cured. In the case of Etienne Dumand, as given by Dupuytren, in the 6th vol. *Repertoire d'Anatomie*, the diseases were combined on the side of the head. Erectile tissue existed in the ear, from which repeated hæmorrhage had occurred. The enlarged arterial branches had been tied by MM. Vopulus and Retif, with very partial benefit, before he came under Dupuytren's care, who tied the common carotid: the disease was arrested, but not cured. Pressure was assiduously employed as an adjuvant, but it also failed. These two cases, therefore, besides others I might quote, prove that ligature of the main arteries, aided by pressure, will not cure radically cricoid aneurism and erectile tissue when combined. As to what treatment will avail, I cannot speak from experience, but, in any future case, I would tie, according to circumstances, the main artery on the enlarged vessel, and immediately thereafter attack the erectile tissue by ligature, setons, excision, nitric acid, or any of those measures which experience has shown us are of use in the uncomplicated forms of aneurism by anastomosis, selecting that method which might seem best adapted for the circumstances of the case under treatment. I should be disposed to try numerous setons combined with pressure. It may be asked, why was not this done at first? I may, perhaps, be allowed to say, that my own wish was to have removed with the knife the first and second fingers with a part of the erectile tissue at their roots, immediately after tying the ulnar artery. But, besides that this was disapproved of by some of my colleagues, under the fear (very likely well grounded) that gangrene would attack the wound, the patient would not submit to it.

The treatment of uncomplicated cricoid aneurism should consist, in the early stages, of rest, cold, and moderate pressure. Breschet's first case shews that the disease may exist in all the arteries of an adult limb, and make great advances, without any operation being requisite.

The circumstances which may require operation are, the rapid progress of the disease, or its having attained such a size as to become a source of serious annoyance or inconvenience. One important question, as regards the period for operation, now suggests itself—whether the erectile tissue be ever superadded as a disease secondary to cricoid aneurism? I am not prepared to answer this question with an absolute negative, but am disposed to say that if it do occur it is rare. In none of the cases which I have seen or read does the cricoid aneurism appear to have been the primary, and the

erectile tissue the secondary, disease; whereas the converse very frequently happens, and occurred in the cases of Dumand, M'Lenan, and one related by Mr. Russel*. If this view be correct, the operation may be delayed in uncomplicated cricoid aneurism to a later period than would be safe in the two diseases combined, or erectile tissue alone.

What operation is required in uncomplicated cricoid aneurism? I have no hesitation in replying that ligature of the diseased vessels should always be tried previous to the more serious operation of tying a sound portion of the main artery. I am well aware that a different practice has been adopted, but, it appears to me, with very questionable propriety. I shall here principally advert to two cases (besides M'Lenan's) which occurred in this city. The first was in the practice of the late Dr. M'Lachlan, and is related in the first volume of the Glasgow Medical Journal, p. 81. This case I consider an example of uncomplicated cricoid aneurism. Dr. M'Lachlan says, "Having explained to the patient the possibility of tying the arteries singly, I began by laying bare the temporal artery as it emerges from the parotid gland; but on dividing the fascia-like substance which kept it in situ, it shot forth through the opening in the form of a loop * * * thinner in its coats, and, if possible, more diaphanous than a vein. A ligature was applied to this loop, the wound was dressed with adhesive plaster, and, for additional security, a firm compress and bandage was applied. It was now evident that the vessel was diseased at the point of ligature, and the propriety of tying the carotid aneurism hence became obvious." The common carotid was consequently tied, and the patient died on the fourth day.

It is obvious that Dr. M'Lachlan feared that an artery affected with cricoid aneurism would not bear a ligature, "and could not be trusted to." Subsequent experience has shewn that this fear is groundless. M'Lenan's brachial artery was "as thin and diaphanous as a vein," yet the ligature acted, in every respect, as favourably as if the coats had been sound: his ulnar artery started "in the form of a loop" through the wound of the operation, and was tied with perfect success. In Dupuytren's case all the diseased branches (and, as the operators believed, the external carotids) were tied, without hæmorrhage or untoward consequences. It is therefore by no means improbable that if Dr. M'Lachlan had persevered in his original method of operating, the result of his case might have been more favourable.

The following case occurred in the hospital practice of the late Dr. Auchincloss, of

* LOND. MED. GAZ. 1836.

this city: I give it, abridged, from the Hospital Journal.

Dec. 19, 1838.—Mary Robinson, æt. 23. On upper and anterior part of left temple there is a round tumor, about the size of a pigeon's egg, slightly irregular on its surface, with a soft doughy feel and a strong pulsatory motion. The integuments covering it are of a purplish colour, increased by excitement, and at the catamenial periods. The temporal artery is very much enlarged from the point where it leaves the parotid gland, and the tumor seems mainly, if not wholly, composed of its large convoluted branches. The disease is congenital, and is said to have assumed the appearance of a very small nævus. It did not enlarge much in the early part of her life, but lately it has been gradually increasing, and is attended with acute pain. General health perfect.

July 7th, 1839.—Yesterday the common carotid was tied in the upper part of its course. "The operation was very tedious, in consequence of hæmorrhage from the thyroid plexus of veins constantly filling the wound on removal of pressure, and completely obscuring a view of the vessel. After considerable delay the vessel was exposed, and a ligature passed round it." The hæmorrhage must have amounted to twenty-five or thirty ounces, and was entirely venous, no artery, except a small cuticular branch, requiring to be secured. On the ligature being tightened, the pulsation of the tumor instantly ceased.

26th.—No unfavourable symptoms, with the exception of bilious vomiting, followed the operation; the tumor is flaccid and smaller; the ligature came away to-day.

March 13th.—Three days ago tumor became painful, vividly red on its surface, "and fully as large as it has ever been since admission, but without the slightest pulsation." By cold locally, and saline purgatives, it is now small, flat, pale, and free from uneasiness.

25th.—Dismissed cured.

I saw this case many months after the operation: there was no reappearance of the disease.

I can have no hesitation in saying, that if a similar case were to present itself I would tie the temporal, and not the common carotid; for although the operation was successful, it proved more difficult, more tedious, and of course more dangerous, than this always severe operation usually is. The reason which induced the operators to tie the common carotid was the dread of tying a dilated artery; a dread which I have already endeavoured to show is without foundation.

Varicose Aneurism and Aneurismal Varix.

One peculiarity of these traumatic aneu-

risms, which associates them with the forms we have been considering, is the enlarged state of the arteries. Dr. W. Hunter was one of the first to show that the artery, nearer the heart than the point where it communicates with the vein, is dilated; and Breschet has adduced cases to prove that, in many instances, especially where the disease is in the limbs, the artery below the wound is also enlarged.

To account for this unexpected fact, Dr. W. Hunter and M. Breschet have each proposed theories diametrically opposed to each other. Dr. Hunter thinks it is owing to the passage of arterial blood into the vein; M. Breschet that it is owing to venous blood passing into the artery. Dr. Hunter says, "It is the consequence of the blood passing so readily from the artery into the vein, and is such an extension as happens to all arteries in growing bodies, and to the arteries of particular parts, when the parts themselves increase in bulk and at the same time retain a vascular structure."

On this opinion of Dr. Hunter, M. Breschet offers a very severe criticism, and accuses him of being a bad physiologist, and inconsistent with himself. In opposition to it he gives it as his opinion that the greater number of the peculiarities of the disease, and this one in particular, arise from the passage of venous blood into the artery. During the systole of the wounded artery arterial blood is poured into the vein, and during the diastole venous blood is poured into the artery.

With all due deference, I must say that M. Breschet's theory has less semblance of truth, and is as little satisfactory, as Dr. Hunter's. Its truth seems doubtful, for the following reasons. M. Breschet himself says that the venous blood passes into the arteries of the extremities only, and not into those of the subclavian or carotid. It appears to me that his reasons for this exception are by no means satisfactory. Secondly in Mr. Perry's case of spontaneous varicose aneurism of the femoral, the artery was greatly dilated, and its coats were thinned, but the vein just below the aperture was obliterated at a single point, below which it was again pervious. In this case the obliteration of the vein must have prevented the passage of venous blood into the artery. Thirdly, dilatation of arteries, of the kind we are considering, frequently occurs when there is no admixture of venous blood. In Dr. McLachlan's case it arose from arteriotomy, and in Mr. Russell's (*MED. GAZ.* 1836) from wringing clothes in washing. Fourthly, the blood in the vein must be principally, if not entirely, arterial. That which it gives back to the artery must be of course of the same character, and the admixture of venous blood in the artery,

If it take place at all, must be in very minute proportions. If the systole of the artery fill the vein with arterial blood, its diastole must allow some of that blood to pass back again, and if the valves should be destroyed by the impetus of the arterial blood and the varicose state of the vein, the vein for some distance from the wound will be filled with arterial blood, and the admixture of venous blood with the arterial in the artery be proportionally small. In farther proof, if any be required, that the veins in the immediate neighbourhood of the wound in the artery are filled with arterial blood, I may relate the following case. I give it from a note taken by the young gentleman, one of my pupils, who saw the patient. It is curious, inasmuch as it is the only case I have met with in which a vein in the immediate neighbourhood was opened by venæ-section.

Case of aneurismal varix.—John O'Connor, æt. 32, on the 25th of Feb. applied to me at the Gallowgate Dépôt, where I was then employed as an assistant by the Glasgow Board of Health, in consequence of his having what I considered to be an acute inflammation of liver, for which I deemed it necessary to abstract blood. On exposing the right arm for the purpose of performing the operation, I was struck with the appearance of a tumor situated at the bend of the arm, on its inner or ulnar edge, and immediately over the bifurcation of the brachial artery where it gives off the radial. Upon examining more minutely concerning it, he communicated to me the following account.

About two years ago, when tipsy, he applied to a surgeon in Greenock (who also was a little intoxicated) to have blood drawn. Accordingly, the operation was performed in the median basilic vein over the site of artery which appears to have been transfixed during the operation: he says the wound of the vein healed as usual, and he did not discover anything remarkable for the space of a few weeks, at which time a tumor was observed over the part where the wound was made: this tumor has latterly increased to about the size of a pigeon's egg, at which it has remained stationary this year past. He suffers no inconvenience therefrom; can pursue his usual avocations with as little inconvenience as before the accident happened.

After examining it pretty carefully I unhesitatingly considered it to be an aneurismal varix, and of course, instead of bleeding in that vein which lay over the tumor, as I had intended, I opened the cephalic, when the blood flowed with amazing violence and rapidity, far exceeding that which I ever before witnessed in any other operation, and besides it possessed the characteristic features of arterial blood; so much so, that one of my fellow students, who was standing by,

immediately exclaimed, "you have trans-fixed an artery;" but upon my making pressure below the wound, it was immediately restrained.

Spontaneous varicose aneurism was reckoned so rare at the time Mr. Hodson wrote, that he had neither met with, nor read, of an unequivocal example of it. Several cases have since been published; but as the disease is rare, I may be excused for adding another to the list of recorded cases.

Widow Cameron, æt. 66, Cotter's wife, Inverary. Sept. 6, 1833, she was sent to me for consultation, and at that time presented the following appearances. On under part of neck, towards right side, is a pulsating tumor the size of an ostrich's egg, of a somewhat triangular form, its basis about six inches, extending from outer side of left sterno-clavicular articulation to beyond middle of right clavicle, and its apex nearly in contact with the right ear. The body of the tumor is tolerably firm, somewhat lobulated on its surface, and pulsates most distinctly throughout. Towards its apex, near right ear, a portion the size of a hen's egg projects from the body of the swelling. It is soft, moveable, easily emptied, and has a strong vibratory motion. To the outside of this projection, and towards outer margin of right sterno-mastoid muscle, the integuments have a very distinct vibratory motion, as if a small bird, or insect, were fluttering strongly under them. The stethoscope discovers strong pulsation and bellows murmur throughout the whole tumor; but over the projection and portion of integument just alluded to, the sound is very loud, whizzing, and struck me as very like that of a large old-fashioned spinning-wheel, driven on a wooden floor over-head. When the finger and thumb, or two fingers, are placed on the outer edge of this tumor, and gentle pressure employed, the whizzing noise ceases, the larger tumor distends and becomes firmer, and the sensation and sound are limited to those of simple but strong pulsation. When the pressure is removed, the noise instantly returns, the tumor slackens, and the strong pulsation diminishes. The carotid artery can be distinctly traced outside (towards the right side) of the tumor, at least half-way down the neck. Running along the same aspect of the tumor, I thought I discovered a very large vein (probably the internal jugular) enormously distended towards the angle of the jaw; pressure on it above the clavicle lessened the thrill of the upper part of the tumor. The veins over the tumor are enlarged. The above, she says, is of thirty years' duration, having begun at the lower part of the neck, and gradually but slowly increased upwards. The soft portion near the angle of the jaw appeared about six

months ago, after vomiting and coughing, and is said to be rapidly enlarging. General health good; has had fourteen children. I have heard of this woman within these few weeks; she is still alive, and the tumor is said to be very much as it was nine years ago.

This case, although obscure, appears to me to be best explained on the supposition of its being varicose aneurism between the common carotid and jugular vein. No treatment was deemed advisable, and the result has proved that the advice was sound.

The treatment of these forms of aneurism ought very generally to be limited to palliation, for two very good reasons—1st, because in the great majority of cases the disease is merely an inconvenience, and no operation is required; and 2d, because ligation of the artery is very generally followed by gangrene of the limb. When an operation is decided on, the Hunterian is not applicable. We must ascertain the point of communication between the artery and vein, and tie the artery above and below the opening in it. Breschet seems to think that this method of operating would not be followed so readily by gangrene of the limb as the Hunterian operation; but, so far as I know, this opinion is not based on a sufficient number of facts. The safe rule is, not to operate unless compelled.

CASE OF LARYNGITIS— TRACHEOTOMY.

To the Editor of the Medical Gazette.

SIR,

I BEG to send you the following case of laryngitis (?), and shall feel obliged by its insertion in the MEDICAL GAZETTE.

I am, sir,

Your obedient servant,

GEO. E. STANGER.

Nottingham, Oct. 10, 1842.

H. Bradley, ætat. 9, a delicate-looking girl of strumous diathesis, has for some time past been subject to hoarseness of voice and occasional dyspnœa, which are always aggravated when she takes cold. I could not ascertain from her mother that this came on suddenly, or at any particular period; but she says she has often noticed that, when she catches cold, her voice and breathing are affected.

She came under my care first on the 23d of February, 1842; she was then an inmate of the Union Workhouse of this town, of which I was surgeon. She was breathing with great difficulty,

every inspiration requiring great effort to perform it, and producing a loud croupy sound. She could not lie down in bed, but was obliged to be propped up by pillows. There was, however, but little febrile disturbance; the pulse was not quicker than natural; the tongue was clean, and the skin only moderately warm. The matron of the house having seen many cases of croup, had no doubt that this was one; and knowing the danger of delay, had very judiciously ordered her to be put into a warm bath, and had applied a number of leeches to the throat before I arrived. On carefully examining the symptoms, I came to the conclusion that the case was not one of pure croup. I formed this opinion partly from the absence of any constitutional symptoms commensurate with the urgency of the dyspnœa, but chiefly from the character of the sound produced by respiration. The obstruction seemed to be so immediately at the orifice of the trachea, giving me the idea that the opening was much narrower than it ought to be. I did not carry on the bleeding to any great extent, but satisfied myself with a little saline medicine, attention to the bowels, and keeping the patient warm; and I was pleased to observe that the symptoms gave way in a few hours, without any cough or expectoration. She remained in the hospital a few days, that I might observe her breathing. It never became quite natural, but was attended throughout with a degree of harshness sufficiently marked to attract the notice of any one who might be in the room. I saw her occasionally after she left the hospital, as she still remained in the workhouse, but she did not require any further medical treatment until the 1st of April, when she had another attack, but milder than the one just described. This attack speedily yielded to purgative and febrifuge medicines, and confinement to bed for a few days.

On Wednesday, June the 1st, in passing through the house, I heard this girl talking, and observed to her mother, who was standing by, that she seemed to breathe and talk worse than usual. She replied that she thought she must have caught cold. On the evening of the same day I was requested to see her, but not being at home, my colleague, Mr. Jolland, kindly attended for me.

He found her breathing with great difficulty: each inspiration being attended with a loud, harsh, croupy sound. Mr. J. immediately bled her from the arm, and ordered a number of leeches to be applied around the throat, an emetic to be administered, and calomel to be given every two hours. Mr. J. saw her again in the morning of June 2d; and as there was no amendment, and the blood drawn presented a slightly buffy appearance, he took away about six ounces more blood from the arm, and directed the calomel to be continued. I saw the child about 11 A.M. She was sitting up in bed, breathing hurriedly, and with great exertion, even inspiration emitting a dry, harsh, grating sound: there was scarcely any cough, and no expectoration. Her countenance was pale, and expressive of great anxiety; pulse rapid and feeble; tongue moderately clean.

These symptoms continued without any abatement during the whole of the day and the following night, which was passed without any sleep; for if the child attempted to doze for a few minutes, she would awake in the greatest anxiety, leaning forwards, struggling and gasping for breath. Still there was no cough; and on listening to the chest, which sounded well on percussion, I could discover no bronchitic or other rales, though these, had they existed, might probably have been masked by the loud and stertorous breathing.

Friday morning.—Symptoms not at all relieved; the paroxysms of dyspnœa occurring every hour with extreme violence, during which an experienced nurse expressed her conviction that the child must very soon die. The face was of a livid paleness, and expressive of the greatest agony; the skin was bathed in perspiration; pulse remarkably quick and feeble. The mercury had not affected the mouth.

R. Ammoniae Carbonatis, gr. iij. ; Tinct. Hyoscym. ℥x. ; Mist. Camph. ʒiv. tertiâ quâque hora sumend.

Evening.—All the symptoms seem aggravated; the paroxysms of dyspnœa coming on every 10 or 15 minutes, causing her to jump out of bed in her eagerness to fill the chest with air. Feeling convinced in my own mind that she could not live through the night

unless such a change took place in her symptoms as I was not warranted to expect, and believing that the operation of tracheotomy was the only resource left, I requested the opinion of my friend, Mr. J. Thompson, an experienced and highly-talented surgeon of this town. He at once concurred with me in the propriety and necessity of the operation, as the lungs appeared to be sound, and the obstruction, so far as we could judge, seemed to be situated in the upper part of the larynx.

The child was placed on a table in a semi-recumbent posture, with the head resting on an attendant. An incision was made, about $2\frac{1}{2}$ inches in length, just below the transverse portion of the thyroid gland; the muscles were then separated, and the deep cervical fascia exposed. The trachea being fixed by the fore finger of the left hand, a hook was passed under one of its rings, by which means the tube was brought well into view; a narrow bistoury was next introduced, and carried round the hook, so as to take out a small circular piece of the trachea. A silver trachea tube was then introduced, and confined by ligatures. Some difficulty was experienced in taking out a piece of the windpipe, from the slipping of the hook, especially as the trachea was very deeply situated, and the child was struggling violently the whole of the time.

If I should have to perform the operation again, I should prefer a pair of hooked forceps, as by their means the trachea might be more securely held. There was not a great deal of bleeding during the operation. The breathing was immediately relieved, and the child began to doze; the pulse, which was 156 before the operation, fell to 140, and the countenance expressed less anxiety.

Saturday morning.—Has slept several times during the night, for half an hour uninterruptedly, but is frequently disturbed by coughing up a quantity of bloody mucus. A hissing noise is produced by every inspiration. Tongue brown, and rather dry; pulse 150, feeble; skin hot and dry.

To have beef-tea, with arrow-root. Sp. Ammon. Co. in effervescing draught, with ℥j. Tr. Opii. 3 horis.

Bowels have been freely opened.

Evening.—Countenance anxious; starts frequently in sleep; breathing

attended with loud hissing noise; other symptoms as before.

Sunday morning.—Appearance somewhat improved; has slept better during the night; skin cooler; tongue still brown and dry; pulse 150.

May have a tea-spoonful of port wine occasionally in a little sago. *Continuentur medicamenta.*

On carefully examining the wound a small flap of trachea was perceived, and on every inspiration it was drawn into the trachea, and obstructed respiration. Mr. Thomson therefore laid hold of it with a pair of forceps, and removed it; after which the breathing became much more natural and easy. The tube was not returned.

Monday.—Has slept well, and taken a good supply of nutriment. The wound looks well and is suppurating freely; skin cool and perspirable; pulse 140; bowels open; tongue cleaning.

Tuesday.—Slept several hours successively during the night. Countenance lively; breathing free and easily; pulse 130; tongue clean; bowels open.

Thursday.—Slept well, but seems rather feverish this morning; pulse 140; breathes freely through the wound, which discharges copiously. Takes food willingly.

Friday.—Slight cough and mucous expectoration; in other respects going on favourably.

On closing the wound with the finger and thumb, the patient manifests very little uneasiness, and breathes through the mouth with very little difficulty.

It is needless to occupy the reader's time with a minute detail of the progress of this case towards convalescence. It may be sufficient to remark, that every symptom was favourable, and in three weeks the wound was quite healed up, and the little patient in as favourable a state as she had been before the last attack.

I had her kept in the hospital for several weeks after she was cured, in order to prevent any recurrence of the disease, and directed her dress to be made so as to cover the neck, and preserve it from exposure to cold; and as there was some hoarseness still remaining, I had a blister applied to her neck and kept open. At the same time she took small alterative doses of mercury, with a small quantity of Vin. Ferri to promote absorption and invigorate the general system. She was

discharged from the hospital on the 26th of August, and up to the time at which I write has had no relapse.

REMARKS.—This case presents several points of interest to the pathologist and to the practical physician. My own impression is, that the obstruction was seated high up in the larynx, and consisted of chronic thickening of its lining membrane, narrowing the tube. A very slight additional inflammation sufficed to increase the mischief, and nearly occlude the passage; hence the immediate relief which resulted from the operation, which not only caused the instantaneous alleviation, but allowed the inflamed part to rest and regain its natural condition. The discharge from the suppurating wound would also doubtless materially contribute to produce this desirable end.

I witnessed a somewhat similar case many years ago, in the practice of my esteemed friend and late master, Mr. Ewen, of Long Sulter, during my apprenticeship to him. The patient had long been troubled with dyspnoea, arising from some thickening about the rima glottidis. This at length became so much increased as to endanger the woman's life. She was almost *in articulo mortis* when Mr. E. performed the operation of tracheotomy; but no sooner was an opening in the trachea effected, than the patient, who but a moment previously had been gasping for breath, said she felt as if she were in heaven. This patient perfectly recovered, and is, I believe, now living and in good health.

MR. LEE ON DUTCH MEDICAL INSTITUTIONS.

To the Editor of the Medical Gazette.

SIR,

I BEG to forward a few brief notes on some of the medical institutions of Holland (made during a few days' tour in that country), which may possibly interest some of your readers.—I am, sir,

Your obedient servant,

EDWIN LEE.

170, North Street, Brighton,
Oct. 10, 1842.

There is perhaps scarcely any city—the two large metropolises, London and Paris, excepted—which possesses so many charitable institutions as Amster-

dam. The chief hospital (Binnen Gasthuis) is an old building in the centre of the town, divided into two parts by a canal, and containing upwards of 600 beds, in long wards of from 70 to 100. Those on the ground floor have a tolerably comfortable appearance; but the wards upstairs are mere garrets without ceiling: the bare rafters which support the roof presenting a desolate and cheerless aspect. These, however, are considered preferable, on account of their being better ventilated. At Amsterdam is a school of medicine; there are besides medical and surgical wards of about 40 beds each. The hospital receives acute and chronic cases, which are under the superintendence of a professor of medicine, a professor of surgery (Tilenus), and assistants. During the visit an *infirmier* attends with a large book, wherein are ranged, in printed columns, the formulæ of the hospital—as *pilulæ opiatae*, *mistura demulcens*, &c.: the professor marking the number of the patient's bed opposite to any one of these which he prescribes; extemporaneous prescriptions being comparatively seldom written. The examination of patients is cursorily performed, and auscultation and percussion appear to be but little cultivated. After the visit clinical lectures are delivered. The most common complaints are the various forms of ague, which prevail both in the town and country, as indeed might be anticipated from the aspect of many districts; and in a large proportion of the bodies of those who die from other diseases, indurations of the liver and spleen are found, indicating the general prevalence of ague. Sulphate of quinine, in moderate doses, is the remedy usually employed in the treatment. Continued fevers are likewise at times extremely prevalent; and in certain localities endemic, and speedily fatal. Diarrhœa is a very common complication from the beginning; but ulcerations of the small intestines is less generally met with in post-mortem examinations than is the case in Paris. Depletions by bleeding and purgatives is rarely employed; cooling saline drinks being for the most part prescribed when there exists special indications for more active treatment. Rheumatism is likewise very common. In the acute form, active depleting measures are not usually had recourse

to. Diaphoretics are a good deal used. Colchicum is seldom prescribed in rheumatic cases.

Acute inflammations of the abdominal and thoracic viscera are not of very frequent occurrence, as is the case in other countries, where the air is more dry and sharp, and the transitions of temperature greater and more sudden. Chronic inflammations of the bowels and chronic bronchitis are very common. Occasional local bleeding, nitre, ammonia, squills, and other expectorants, and the application of blisters, are the remedies mostly employed. Nervous disorders, which were formerly very common among the higher orders (which circumstance was ascribed to the too frequent use of tea), at the present time less frequent.

From the comparative absence of carriages in the streets, serious accidents are of less frequent occurrence than in most other capitals. Scrofulous diseases, especially those which affect the articulations, are extremely prevalent; and a ward is appropriated to children affected with these diseases. Iodine is not given in these cases, but local counter-irritation, by means of issues, is most frequently employed; the oleum jecoris aselli (which is likewise very generally employed in Germany in many chronic complaints, but which is scarcely to be met with in England) being administered internally*. Stone, which in former times was considered to be very frequent at Amsterdam, is now but rarely met with. Professor Tilenus states that he has not had more than eight or ten cases within the last thirteen years. Fractures of the leg are treated by pasteboard splints and starched bandages, in simple cases: under other circumstances the limb is placed in a junk. In fractures of the thigh, the extended position is preferred; a splint being fixed on either side of the whole length of the limb. From the number of vessels arriving at Amsterdam and Rotterdam from long voyages, scurvy is not unfrequently met with in the hospitals.

* Mr. Bennet has recently published a work on the use of the Cod Liver Oil.

MIDWIFERY CASE,

IN WHICH THE PLACENTA WAS FOUND
THICKLY STUDDED WITH SMALL
POINTS OF BONE.

To the Editor of the Medical Gazette.

SIR,

IF you deem the following case of sufficient importance, its publication will oblige,

Yours most respectfully,
JOSEPH BELL.

Barrhead, Oct. 13, 1842.

April 24th, 1841, half-past 11 o'clock A.M.—Mrs. S., æt. 22 years, a stout female, a native of the north of Scotland: second pregnancy. Has been in labour since 8 o'clock A.M. Os uteri nearly dilated; head presenting, with occiput to left groin, and is entering cavity of pelvis; the waters are away; pains strong; patient very restless; pulse 70. Her pains continued good, and at half an hour past 1 o'clock P.M. a large female child was born. Five minutes afterwards a pain expelled placenta into vagina, from which it was extracted by the hand. In doing this my fingers were severely pricked. On examining the placenta, I ascertained the cause of this to be a number of small sharp points attached to the placenta. On more minute examination, its uterine surface was found to be covered with a milky-coloured membrane, which was thickly studded with small points of bone, as sharp as pins, about one-eighth of an inch in length, and about the thickness of a fine sewing-needle. On examining the substance of the placenta, it was found completely filled with these points, but they were of a much larger size, some rather more than two inches long; they were running in every direction, ramifying not unlike the air-tubes in the lungs. The umbilical veins presented nothing unnatural; but the artery, at its termination, was partially ossified. No hæmorrhage, but severe after-pains. She had an excellent recovery, and had enjoyed good health during the period of pregnancy.

ON THE DETECTION OF ALBUMEN
IN URINE.

To the Editor of the Medical Gazette.

SIR,

I SHALL feel obliged by your giving the following observations a place in your valuable journal.—I am, sir,

Your obedient servant,
J. W. GRIFFITH, M.D. F.L.S.

9, St. John's Square,
Oct. 15, 1842.

1. *On the detection of albumen in urine.*

The solubility of albumen in nitric acid, as a source of fallacy in detecting albuminous urine, has, I think, been entirely overlooked by writers on urine. The ordinary method of proceeding is to heat the urine to the boiling point, and then to add a few drops of nitric acid, when, if the precipitate be redissolved, albumen is considered absent; if otherwise, it is regarded as present. When the urine contains albumen in large quantity, the appearances produced by its coagulation are so characteristic that they cannot be mistaken: it is only when there is a moderate or small quantity present that any error can be made. The strong acid being generally used, I shall confine my observations to it.

When a few drops of nitric acid* are added to urine† containing a small quantity of albumen, a cloud is immediately formed, which, by agitation, is entirely redissolved: so, after heat, a drop or two of acid added and the fluid agitated, the albuminous cloud disappears; a few drops more added, throw it down again; and a further considerable excess redissolves it. Therefore, the formation of a cloud by heat, which is soluble in a drop or two of nitric acid, is no proof that albumen is absent. The value of the nitric acid test depends entirely upon the proportion added. The mere adding a few drops is not sufficient; moderate excess ought to be used. The quantity of acid required for the above-mentioned second solution is, on an average, at

* Specific gravity, 1.5.

† I suppose the operator to be using about six drachms of urine.

least as much as the bulk of the urine used; so that by always using considerably less than its bulk, this chance of error may be avoided. The cloud of phosphates precipitated by heat is very readily dissolved in a small quantity of acid; and by adding a few drops more it is not again precipitated. This, then, would readily distinguish the phosphates from albumen.

2. The following is an account of a crystalline urinary deposit, differing essentially from any hitherto described. It was passed by a patient in St. Bartholomew's Hospital, who is 32 years of age, and has a large hepatic tumor, with anasarca and ascites. The crystals have only been found once, although the urine has been continually examined for a considerable period. They are four-sided flattened prisms with dihedral summits, and possessing a curious internal structure. They were entirely dissipated by heat; soluble in nitric and muriatic acids, solutions of potassa and ammonia; insoluble in water, alcohol, ether, and acetic acid. After solution in dilute nitric acid, and evaporation, no pink residue was left: the solution in ammonia gave no crystals of cystine by evaporation, nor did the crystals contain any sulphur. The urine which contained this deposit was acid, of a deep brownish amber colour, containing the ordinary proportion of mucus; sp. gr. 1.037: contained great excess of urea; no bile. The urine passed since that time has continued diminished in quantity; of the same dark colour, contains a deposit of lithate of ammonia, with great excess of urea; so that on standing for two or three hours, a portion of carbonate of ammonia is formed, which causes the urine to effervesce with an acid, and to contain a copious precipitate of triple phosphate. The lithic acid obtained from this urine by nitric acid is almost black; and on the addition of an equal bulk of nitric acid the urine turns of a very deep colour.

N.B. Since this was written, the patient has died: the liver was found very much enlarged, weighed fifteen pounds, and contained an enormous quantity of melanotic deposit.

ON DISEASES OF THE BRAIN.

By E. COPEMAN, M.R.C.S.

(For the *London Medical Gazette*.)

IN the number of the LONDON MEDICAL GAZETTE for Dec. 25, 1840, I published a paper on the treatment of certain diseases of the brain, in which I ventured to express an opinion that the common method of treating apoplexy by large bleedings was injurious. From subsequent study and observation, I am still more convinced of the impropriety of the general practice, and feel assured there is a greater chance of restoring apoplectic patients by treating them according to the principles advocated in the paper alluded to. The first case there published was that of a gentleman upwards of 70 years of age, who had suffered and recovered from three successive fits of apoplexy, the last occurring in May 1840. On the 2d of February, 1841, this gentleman was again attacked with vertigo, followed by insensibility of at least half an hour's duration. He was roused a little with strong hartshorn, and made to swallow an ipecacuanha draught as formerly, which produced vomiting and a gradual return of sensibility. His bowels were afterwards kept free with senna draughts, and he recovered in a few days. On the 24th of Dec. in the same year, he was again attacked in a similar manner; but although the same means were effectual in removing the apoplectic symptoms, he was left weaker for a month or two than he was before his illness. I attended him again in May 1842, for a cold and sore-throat, from which he soon recovered; and by the help of mild tonics and aperients he became as well as usual. On the 15th of June, 1842, I was called up early in the morning to see this patient, who had been suddenly attacked with loss of sensation in the cheek and limbs of the left side. He was sensible, although somewhat confused and alarmed. No pain or uneasiness in the head; pulse not very steady, and I discovered a hardness in the artery indicative of approaching ossification; no loss of motive power in the limbs. He took his usual emetic draught, but it did not act; afterwards, aperient

medicine, keeping to his bed. By the use of these means, and rubbing the affected parts with strong liniment, sensation was restored perfectly in the shoulder, arm, and thigh; imperfectly in other parts. Power of moving the limbs perfect, and in a few days he was able to get down stairs. At the present time, the only parts in which the sensation is not perfectly restored are the left cheek and the left hand. He complains of this hand being generally cold and stiff, although it is of equal temperature, and as perfect in its movements as the other. He is certainly more feeble, and generally feels languid and faint after breakfast, but he takes a dose of tonic medicine daily at 11 o'clock, and is pretty well during the rest of the day. A few days since, he complained of slight vertigo and double vision the morning after a journey of 22 miles, but rest and careful diet soon removed the symptoms.

Is not the case of this gentleman one of unusual occurrence, and full of instruction? Five attacks of apoplexy (some of no little severity), then one of anæsthesia, and the patient, although feeble, enjoying as much health as most men of his years! Can there be any doubt but that the only way to prolong his life is to support his nervous power? Can there be a doubt but that the usual treatment by bleeding would render his attacks fatal? And yet he is corpulent, short-necked, apoplectic-looking, with a good appetite, capacious stomach, and generally a good pulse.

CASE II.—Mrs. A. æt. 41, of exceedingly nervous temperament, and easily-excited circulation, stout, and scarcely ever taking exercise, was attacked in the morning of Friday, Nov. 20, 1840, with pain in the muscles of the neck and back of the head. Directly after a light dinner, eaten without appetite, she saw an unnatural brightness before her eyes, soon followed by loss of vision and numbness in the right side. She then lost the power of speech, the right leg and arm being cold and paralytic. I was soon on the spot, and found her sensible and making attempts to speak. The limbs were numb, and she was not able to close the hand. Pulse frequent, but compressible. I ordered her feet to be

put into warm water, and the following draught.

R Inf. Sennæ, ʒj. ; Magn. S. ʒij. ; Sp. Lav. c. Tr. Jalap. aa. gttss. xxv.

At 10 P.M., she had vomited three times, and the bowels had acted once. She had regained the power of articulating, and moving the limbs, but felt "very ill."

Empl. Lyttæ Nuchæ.

21st, 9 A.M.—Has had no sleep, and complains of soreness in the scalp. Limbs not paralytic; speech more perfect; pulse soft and rather frequent; tongue furred.

Ordered some purgative pills.

6 P.M.—Has been much griped by the pills, and vomited bilious matter twice; bowels acted once since morning; movements of the limbs all perfect; pulse soft; perspired freely after vomiting.

22d.—Pain in the muscles of the head and neck, with great tenderness of scalp. Pulse 72, soft; tongue clean; no fever; no paralysis.

Fotus papav. t. d., and the following draught:—Tr. Colch. gttss. xxv. ; Tr.

Hyos. gttss. xv. ; Mist. Camph. ʒj. iii.

Bowels open.

26th.—Pain in left ear and side of head, superficial and lancinating. Fainted after fomentation, and felt very languid all the evening, but more free from pain: griping and nausea.

Omitt. Colch.

28th.—Better in all respects.

Opiate liniment to the scalp.

This patient soon recovered, without a return of paralytic symptoms.

During the present year (1841), this lady has experienced a similar attack of paralysis, which soon passed off under a similar mode of treatment. I had, some time before her first attack, attended her in an attack of hæmoptysis, and a year or two before she had experienced a severe attack (as I am told) of inflammation of the bowels; which circumstance would probably have been considered indicative of a too active circulation, and have led to bleeding as a proper means of treating the paralytic attack: but I have reason to be glad that I was guided by present circumstances, and not upon any theory

based upon the previous history of the patient.

On the 24th of June, 1842, I was sent for, between 9 and 10 o'clock, to visit this same lady. The message was urgent; and I found her labouring under a fit of apoplexy. She was lying on her back, in bed, with the head stretched out backwards, the skin hot, breathing stertorous, grinding of the teeth, pulse full and resisting. When I touched the soles of the feet she was sensible of it, but I could not rouse her to speak. Pupils dilated, and insensible to the light of a candle. For the last few weeks her servants have observed her to drag the right leg upon the ground in walking. She went up to bed tired and unwell, but had been much as usual during the day. Had been subjected to some mental excitement in the evening. After being up stairs a short time, she rang the bell for the servant, who found her sitting in a chair unable to give her any directions. Soon after, she vomited a little, was assisted into bed, and able to tell her servant she had a great deal of pain in her head, and wished to lie down. Soon after lying down she had convulsive movements in her arms and the muscles of the face. I was immediately summoned, and found her in the state I have described. From the state of her pulse and skin, her age (43), and a feeling that almost any other surgeon would think it right to bleed, I opened a vein, and drew about eight ounces of blood. The pulse rose, was quite free, and became more rapid without losing its power; but the skin cooled, and I determined not to allow more to flow. The grating of the teeth ceased, and I endeavoured to make her swallow some aperient medicine, but as soon as it was in her mouth it excited vomiting, and she ejected some undigested food from the stomach. She now breathed without stertor; pulse of fair strength, and about 80. The vomiting was followed by general perspiration: she attempted to raise herself in bed, opened her eyes, but could not speak. Mustard poultices to the feet were then applied, and I waited a while to watch the effects of the treatment.

At 1 A.M., she was more roused, answered several questions, and expressed by signs a desire to pass urine, which she did in fair quantity. A

second attempt to give her medicine again produced vomiting, and was not persevered in, as she seemed tired, and the skin was becoming cool.

25th, 9 A.M.—Asleep, but breathing slowly, without stertor; pulse much weaker, 72; had been more sensible early in the morning, and had swallowed a pill, which acted on the bowels half an hour before I visited her; countenance pallid; was unwilling to be roused, and very languid; skin warm; frothy mucus in the mouth.

Empl. Lyttæ. Nuchæ. Catapl. Sinap. cruribus. Gave a little barley water, which the stomach soon rejected.

1 o'clock.—Much the same; fresh sinapisms to the feet, the others not having had any effect. Met a physician in consultation, who advised the head to be shaved, and five grains of calomel to be given directly.

7 P.M.—Still drowsy, but sensible when roused; swallowed a draught of Inf. Sennæ and Potass. Tart. Bowels not open; breathing natural; pulse 80; scalp hot. Blisters to the calves of the legs.

26th, 9 A.M.—Removed and dressed the blisters. Scalp hot, and skin warmer than yesterday; pulse 80, of fair strength. Appears conscious of what is being done for her, but cannot articulate; has pain in the head; breathing natural; tongue loaded; no relief from bowels; was raised up in bed, and drank some tea; seemed fired with the exertion. Catamenia appeared yesterday morning.

11 P.M.—Breathing more difficult; but during my visit the bowels were relieved, and the breathing again became free.

27th, 9 A.M.—Skin warm; pulse 86; scalp hot; slight stertor. Swallowed another purgative draught and some barley-water, but with difficulty.

2 P.M.—Bowels relieved again; no stertor; pulse 80, more feeble.

9 P.M.—Blister to left side of the head, where she gave signs of pain. Took three grains of calomel.

28th.—Passed a restless night, and at 5 o'clock A.M. had a violent convulsion: much annoyed by the blister, which I removed. Between this and noon, she had eleven attacks of convulsion; the breathing became difficult; the countenance purple; and the pulse 144. It seemed as if some fresh mischief to the brain had accrued, and

that the case had become hopeless. In the evening, I found she had been free from convulsion for some hours, and had been almost incessantly moving from side to side with all the regularity of an automaton. A little wine and water had been given. The breathing was easier, and the pulse dropped to 100.

29th.—Passed a quieter night, and is more sensible to-day than she has been yet. No relief from bowels; no power of speech; rather more of swallowing; has taken a little wine and water and mutton-broth; skin cool; pulse 70; tongue furred; knows persons in the room; lies in a calm quiet state, with no expression of suffering.

10 P.M.—At 3 o'clock this afternoon the muscles of the face became convulsed, and remained so six hours without interruption, but the limbs were quiet; the heat of skin increased considerably, and the pulse rose to 100; no relief from bowels; breathing impeded. Cold water to the head, and a purgative injection (which soon returned), cooled the surface; the pulse is now 84, and the convulsions have ceased.

30th.—No return of convulsions; more conscious to-day than at any previous time since her illness; swallows better; skin too warm, and face flushed; pulse 80; no relief from bowels. Two injections have been given to-day without effect.

9 P.M.—Bowels freely relieved; was much cooler in the afternoon.

July 1, 9 A.M.—The physician who attended with me was willing to confine the treatment to a repetition of purgative enemata. Pulse 80; more consciousness; no paralytic affection of limbs; articulation and power of swallowing improved.

9 P.M.—Has had two injections, and bowels relieved twice. She is now cool, and gradually improving. Pulse 70, soft; no pain in the head.

2d, 9 A.M.—Slept several hours; breathing quite easy and natural; takes mutton-broth; pulse 80; consciousness and articulation more perfect; bowels relieved twice, the last motion of a healthy colour and consistence; all that had passed previously were dark and offensive: skin cool.

3d.—Slept nearly ten hours. Speaks better; swallows well. Purgative injections repeated daily.

6th.—Improving. Head shaved again.

7th.—Bowels acted well this morning of their own accord.

8th.—Sat up in a chair for an hour. Took a pint and a half of meat-broth, with bread, in the course of the day.

13th.—Injections continued; bowels acting well; pulse 80; skin cool; begins to take solid animal food; is quite sensible, and articulates pretty well.

14th.—Is quite cheerful to-day. Applied caustic for an issue on the arm.

24th.—Got down stairs to-day, and remained there some hours. No paralysis; issue discharging; all going on well.

September 20th.—Is drawn about her garden daily, weather permitting, in a chair upon wheels. Bowels acting; issue discharging; and in every respect as well as before her illness. Catamenia appearing regularly.

In this case the first symptoms of amendment appeared to arise from the vomiting of undigested food; but as a few ounces of blood had been drawn just before, it is not certain to which the improvement was attributable. During the progress of the case I found, that although the heat of skin and flushing of countenance were occasionally very great, the temperature could be reduced, and the force and frequency of the pulse diminished, by very simple means; and that at other times there was a deficiency rather than an excess of action in the system. Cold applied to the scalp, and purgative enemata, always answered the purpose; indeed, the good effects of the injections (composed of senna, salts, castor oil, and barley gruel) were strongly marked, and they constituted by far the most important part of the treatment: and I feel obliged to the physician who attended with me for his forbearance with regard to the use of the lancet, at a time when his inclination seemed to lean towards more depletory measures than those which were adopted. If the patient had been reduced by bloodletting, and had not rallied, her difficulty of swallowing would have prevented food being taken in sufficient quantity to support her strength: what could then have been done to save her life?

[To be continued.]

MEDICAL GAZETTE.

Friday, October 21, 1842.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
 publicum sit, dicendi periculum non recuso."

CICERO.

THE COLLEGIATE SYSTEM.

WE trust that no apology will be needed on our part for again drawing the attention of our readers to a subject which has already been brought before their notice in this journal. The importance of such a matter is so great as to render it imperative on all who are anxious for the welfare of the rising members of the profession, still more on those who are more immediately concerned in superintending and directing their progress, to give it a fair and careful consideration: and this forms to us a fully sufficient excuse for our recurrence to the subject. It is not a question to be dismissed cursorily, as the mere speculation of a moment which is likely soon to die away, and be no more heard of. On the contrary, there seems a growing probability that it will be carried into effect, and will produce great changes in the whole system of medical education.

A favourable impression of the advantage that might be derived from the application of a Collegiate system to medical education is daily gaining ground, and we may fairly anticipate that medical colleges in London will, ere long, cease to be merely things talked of—mere airy edifices, seen only with the imaginative eye of their constructors, but will obtain for themselves a tangible foundation of substantial masonry. Rumours have for some time reached us that projects of the kind are entertained by the leaders of the larger metropolitan schools, and we find that the chance of their being

realized is, in one or two instances, far from improbable.

We may be pardoned for watching with some degree of pride the growing opinion in favour of the benefit that may arise from the application of this system to schools of medicine, and for reminding our readers of the share which the pages of this journal have had in the origin and progress of this sentiment. In them the idea was first proposed and advocated, and should we be fortunate enough to witness the realization of the scheme, we shall have no small degree of pleasure in reflecting on the influence which the MEDICAL GAZETTE may have had in bringing about an object apparently so desirable.

The importance of the subject to future generations of medical students, and consequently to the whole body of the profession, will be acknowledged by every one who is sensible of the extreme value of the time which is occupied by attendance at the schools in London, after the period of apprenticeship is concluded. The few years thus spent may be considered to constitute one of the most important periods in the life of each medical man. The foundation is then laid upon which the future character is to be built; and the opportunities then enjoyed of acquiring information in the elementary parts of the profession, without a knowledge of which the higher branches remain veiled in comparative doubt and obscurity, can, in most instances, never again be obtained. The station which each one is to take in after life, not only as a member of the profession, but as a member of society, is often, indeed we may say generally, then determined. The stamp of future character is then given—habits of industry and application, or the contrary, are formed; and most men are able to trace the origin and cause of their excellencies and deficiencies back to the impressions

which they at this time received, and to the employment of the time which was then at their disposal. There is a period in the life of almost every individual at which the cast of future character is given; and as Gibbon traced the foundation of his future greatness to the first eighteen or twenty months after his arrival at Lausanne, the medical man is perhaps able to attribute the formation of his manners and ideas to no one period so frequently as to the time spent in *walking*, as it is, or rather was, termed, the hospitals in London.

How incalculably valuable, then, is this time; and how essential that every means should be taken to direct its proper employment. Of the importance of the subject we need say no more: it is of itself sufficiently striking; and we cannot forget the duty which is incumbent upon all, not hastily to reject, but to give a careful consideration to, a proposition, the sole object of which is to promote the better superintendence, and more judicious management, of this time.

That some alteration is required in the course of medical education at present adopted, is, and long has been, the universal cry; and no wonder, when we consider that students are collected together in this great metropolis, and allowed to follow their own devices, without the least superintendence or control being exerted over them, beyond a slight obligation to attend a given number of lectures, &c. They are turned loose into the world, without restraint and without direction, at the very period when guidance is most required. They are exposed to all the evils attendant upon the assemblage of young men, without the compensating discipline which is necessary to maintain any thing like good order. It is a system so evidently wrong that one only wonders at its long continuance. And this laxity, or rather total absence,

of discipline has been attended with a corresponding idleness and looseness of morals. Youths, delighted with this freedom from restraint, are determined to make the most of it; and too often squander away the time allotted for their education in frivolous pursuits, to say nothing of a worse employment of it. Any fears of being "plucked," the only thing likely to disturb their peace of mind, are speedily subdued by the comfortable assurance of the grinder's infallible power "to get them through" with a few weeks' work, and they go on, unmolested and unchecked, in whatever course may best be suited to their inclinations.

We do not pretend to draw this picture as representing the whole class of medical students; but it is, unfortunately, we fear, too generally accurate. The tide does not all flow one way; there are various undercurrents in different directions; and the question comes whether an attempt might not be made, we do not say to restrain it altogether, but to moderate and check it—whether some system of superintendence might not be advantageously had recourse to, a little more effective than that which is at present adopted.

The deficiencies in the present regulations in this respect, which have long been apparent, now become more strikingly so, and more urgently require to be altered. The period of apprenticeship being, in most instances, curtailed from five to three years, and frequently omitted altogether, the students come up to London at an earlier period than they used to do, and consequently are more in need of superintendence. The greater advance, too, of medical science, and the wider range of subjects which it is now necessary to become acquainted with, render it still more important that the time which is to be devoted to the study of the various subjects should be well employed and carefully regulated.

We would not have it supposed that we imagine any charm to be necessarily connected with a College mode of life, or that any benefit is to be the result of the mere assembling the students, and giving them a place of abode, near their hospital. We consider such a plan advantageous chiefly as affording the opportunity for carrying into effect something like a system of discipline. The insufficiency of the present regulations are so obvious, and the difficulty of improving them so great under the present condition of things, that we advocate a Collegiate system as affording the best, perhaps the only, opportunity of restraining the licentious, as well as directing the studies of the industrious.

At the same time we are not forgetful of the fact, that many difficulties and practical inconveniences will be found to attend the assemblage of young men in London, which do not exist, or at least are felt in a less degree, in our smaller University towns of Oxford and Cambridge. The same strictness of discipline, especially with regard to those students not actually resident within the College walls, cannot, it is evident, be maintained, and the same precautions cannot be used to preserve order and regularity. But we are not aware that the difficulty, or even impossibility, of attaining to perfection, is any argument against the attempt to attain to, and enforce, a certain degree of discipline. If it cannot be carried out in its fullest extent, is it therefore to be neglected altogether? Are those persons who have at heart the real interests of the students to stop their exertions because they find some difficulties in carrying out their scheme? The very cause which is an obstacle to perfection forms in this instance one of the strongest reasons for making an attempt to establish a certain amount of discipline.

We are at the same time willing to confess, that there are some positive evils which, it is to be feared, will be found more or less connected with the system we advocate; but these will depend, in a great measure, on the manner in which it is carried out. If it is to be considered merely in the light of a convenient mode of accommodating students, and if the discipline and regulations are to be merely formal, we can conceive the evils to be so great as to render it altogether objectionable. To construct a college, and assemble a number of young men within its walls for the mere convenience of lodging, without subjecting them to authority and strict regulations, would be worse than useless. They had better remain as at present, and be allowed to shift for themselves. But such is not the plan we advocate. We are desirous of promoting the collegiate system chiefly as a means of exercising authority and control over the students, and as affording a means of filling up that important blank which has so long and severely been experienced in the course of medical education.

The system in favour of which we have said thus much is not one to be forced upon the opinions of our readers; it is one for which we merely ask a fair and candid consideration on the part of those who are acquainted with the circumstances in which medical students stand, and who know the difficulties that would attend the practical application of such a system, as well as the advantages which might be anticipated from it. We are glad that it has already received so much attention, and been so favourably esteemed, by those who must be esteemed good judges; and we feel, therefore, the greater boldness in again advocating it. Should it, upon further deliberation, be found impracticable, there will be no reason to regret that the subject has

been brought before the consideration of the profession. Should it, however, as there seems every probability that it will, be found compatible with the position of medical students, and likely to promote their welfare, we shall rejoice in having been the means of promoting so great an improvement in the management of medical education.

THE HOSPITALS OF ITALY.

By DR STRICKER.

THE universities of Padua and Pavia are arranged entirely on the Austrian footing; in the others all the lectures are gratuitous. There is but one course in the year; the vacation consists of July, August, September, and, by an abuse, of October also. To this must be added the numerous holidays, so that the number of lecture-days is often very limited; in Luca, for example, only 143. Hence the time of study is continued pretty long: in the States of the Church, for instance, there is a philosophical course lasting two years, with an examination; then three years' study for surgeons, and four for physicians; and, lastly, two years' practice in the *clinique*, after taking their degree, before admission to the state examination. The practice of physic is more or less governed by three different systems; first, by Rasori's doctrine of contra-stimulus, of which Tommasini is the chief support; by Bufalini's system, who tries to explain diseases by organico-chemical disturbances; and by Pucinotti's, who endeavours to explain them by magnetico-electric disturbances; though the theories of the two last have but little influence on their practice. The treatment is on the whole simple, with much reference to diet: new remedies are admitted with difficulty, so that the *oleum jecoris aselli* (cod's liver oil) is not yet known in southern Italy. Homœopathy has found but few adherents, and hydropathy none. The *cliniques* are partly in the French style, as at Naples and Rome, where they are nothing more than lectures; and partly after the German manner, and at the bedside of the patient. *Polycliniques* [*i. e.* dispensary visits, together with pupils, at the patients' homes] are not usual.

In surgery and midwifery there is a great inclination to the practice of the French, whose principal works are translated into Italian, and whose instruments are used by preference. In the treatment of eye diseases they follow German authors more.

Milan.—The Civil Hospital, *Ospedale maggiore*, is a building one floor high, containing eight courts, which are surrounded by colonnades. It was founded in 1456 by Francis Sforza, and endowed by Carcano in 1610, and by Machi in 1797. Every year, on Lady-day, the portraits of all the benefactors of the hospital are exhibited: they are half lengths, or three-quarters, according to the sums they gave. It contains 2000 beds, and the director is Dr. Caraguti. This institution has its own mill, bake-house, and slaughter-house, which lies in the direction of the Naviglio. It likewise has a small museum of morbid anatomy, collected within these few years. Connected with this establishment are St. Catharine's Foundling Hospital, which receives 3000 children annually, and the Senavra Asylum, containing 300 lunatics; special permission is required to visit either of these institutions. The Hospital of the Compassionate Brethren is spacious and clean, like all which belong to this benevolent order.

Venice.—The numerous small hospitals, which existed in the time of the republic, for single diseases, have been united in the *Ospedale civico*, which is established in the monastery of St. Mark. The director is Dr. Troys. The female lunatics are under the care of Dr. Fassetta, the surgical patients under Professor Rima, the medical ones under Dr. Mengrado. Besides the usual causes of insanity, the pellagra is here an additional one. The institution possesses a very beautiful church, and a small but interesting cabinet of morbid anatomy.

Bologna.—We are especially reminded of the ancient splendour of this university, with which only Padua could compete, by the anatomical lecture-room, adorned with the busts of Mondini, Aranzi, Varoli, and Malpighi, who all taught here, and with the two celebrated flayed figures cut in wood, by Ereole Lelli. The present professor of anatomy is also a Mondini. The cabinet of anatomical wax figures is very old, and distinguished as a work of art, but far less complete than the one at Florence. The cabinet of morbid anatomy also contains numerous wax preparations; and the diseases of the skin and of the organs of generation are represented with particular success. The physical cabinet is exhibited in six rooms; at the entrance is a monument to Galvani. The obstetrical collection is the first of the kind in Italy; it contains embryos from the twentieth day onwards, and a series in wax, representing the normal and abnormal course of pregnancy.

The *Ospedale maggiore o della vita e della morte* is also a military hospital; it is very clean, and usually contains only from 160 to 200 patients, though capable of

holding 800. Here are the *cliniques*; Dr. Cornelli is the director of the medical, Venturoni of the surgical one.

The *Ospedale Sant' Orsola*, in front of the *Porta Sanvitale*, is for chronic diseases; there is one ward for phthisical, and one for syphilitic patients. It is less clean than the last one, and the patients are very irregularly classed. Daveri is the director of the surgical, and Paolini of the medical division: Gualandi is the director of the insane. They have no occupation, and the attempts at cure are therefore attended with little success. Here, likewise, the pellagra is an occasional cause of insanity.

Naples.—In Naples there are three institutions for the study of medicine.

1. The University.

2. The Medical College in the neighbourhood of the *Incurabili*, for 120 young persons, who pay ten ducats a month. They have dormitories, a garden, and a public refectory; are present at the university lectures, and afterwards become assistants at the *Incurabili*.

3. The professors not yet appointed to chairs receive fees, for which they give lectures and hold a *clinique*. To the last belongs the medical *clinique* of Dr. Prudente, which he holds at the patient's bed-side, in the hospital of the *Madonna di Loreto*. Prudente also gives lectures on anatomy in the small lecture-room of the hospital. This hospital contains a collection founded by Pietro Sorrentino, which extends over the domain of mineralogy, botany, zoology, and anatomy. It possesses many wax preparations, *e. g.* the aurantiaceæ, the mollusca (which, however, have their natural shells), the diseases of the eye and the skin, and the varieties of the arteries according to Tiedemann. Giampetri is the director of the surgical division.

The principal civil hospital is the *Ospedale degl' Incurabili*, in an open situation on a small hill at the limits of the old town. It is capable of holding 2500 patients, and has a revenue of more than 100,000 ducats. It contains the university *cliniques*, the medical one, and the surgical one under de Horatiis, where the representations of interesting cases, which are suspended on the walls, cannot be very cheering to the patients; the eye *clinique*, which, since 1822, has been under Quadri; and the obstetric one under Cattolica. The last has 45 beds for pregnant women, two beds for delivery, and an apartment for lying-in women. Besides the wards for patients, which are very large, and built in the form of a cross, the building contains a room for lithotomy; a ward for mercurial frictions; one for phthisical patients; and one which serves as an *hospice* for old incurable ones; in addition to lec-

ture-rooms, an anatomical theatre, a small *clinique* for examination, and an apartment for patients who pay 12 or 18 ducats a month.

Patients who want to be taken in, assemble in the morning in two wards, and are then selected.

The *Albergo dei Poveri*, also called *Reclusorio*, or *Seraglio*, the great building at the end of the *Strada Foria*, was originally intended to be a square, but the front alone has been completed. This enormous poor-house, founded in 1742, contains 2700 men and boys, mostly foundlings, who wear a uniform, and 700 women. In the lower rooms are workshops of different kinds; glass furnaces, a type foundry, a pin manufactory, a forge for arms, &c. The dormitories are airy, and contain from 56 to 128 beds each. The diet consists of bread, soup, macaroni, and wine for dinner, and soup, with bread, for supper; and three ounces of meat on Sundays, Thursdays, and holidays.

In the same building is the institution for the deaf and dumb, containing 32 pupils under the care of Cozzolino, who are instructed in religion, reading, writing, arithmetic, geography, and natural history. The patients of the *Albergo* go to the hospital of *St. Madonna di Loreto*.

Close by is the Botanic Garden, whose director is Tenore, and whose gardener is Denhardt, a Hanoverian. It contains a beautiful *tepidarium* of the Doric order, entirely covered with *Ficus stipulata*; the *caldarium* contains nothing but coffee-trees. The arrangement of the aquatic plants is bad. The plants are arranged in four squares according to Linnæus, and in two according to Jussieu.

The institution for the blind, *St. Giuseppe e Lucia*, on the Chiaja, is arranged after the pattern of the best institutions of the kind. One hundred and sixty blind persons are instructed in reading, music, mathematics, and geography; and they print their books themselves with letters in relief. There is among them an interesting case of *elephantiasis leonina*. The Director is Professor Quadri.

The Naval Hospital is also on the Chiaja; the best wards, which are on the first floor, are occupied by the marines; those on the second, by patients from the galleys.

In front of the Capuan Gate, in the Hospital of Prisons (*San Francesco*) is the anatomical, zoological, and pathological cabinet collected by Naula, formerly Professor of Anatomy. It contains many most remarkable specimens. For example, there is a specimen of quintuplets, four female and one male; they were born at 6½ months, and one lived a quarter of an hour, another

half an hour. There is also an ossified ovary weighing $9\frac{1}{2}$ pounds. The collection, which is elegant but ill arranged, has been bought by the Government, and after the decease of the present possessor is to be transferred to the University. Near it is the hospital called *Sta. Maria della Fede*, for girls of the town; the Director is Giampietri. There is an examination every Wednesday; when cured they are kept a week in the house and observed. The sores are touched with nitrate of silver. When the chief disease is in the glands, the general treatment consists of [mercurial] frictions; when the bones principally are affected, of Dupuytren's sublimate pills. According to the principles which prevail here, the patients have nourishing diet; eleven ounces of bread, with three of meat, four of macaroni, and a tumbler of wine, for dinner; soup, with six ounces of bread, for supper. Schultz's work on the mineral springs of Naples (Berlin, 1837) may be consulted for information respecting the baths of Castellamare and Ischia; observing, however, that the baths of *Torre dell' Annunziata* have already failed.

Aversa.—The first stage on the road to Capua is the little town of Aversa, containing four mad-houses, with more than 600 patients. *Sta. Maddalena*, *Sta. Costina*, and *Capuzzini*, are for men, *Monte Vergine* for women. *Il Reale Morotrofo di Sta. Maddalena* was newly arranged in 1834; the mode of life in it is as follows:—At 7 o'clock the patients rise, and are amused with billiards, occupation in the garden, and music, till noon; their first meal is at 11, the second at 5; then they have a walk in the court-yard, or the pillared hall; and about 7 in the evening they assemble in the apartments. The diet varies in three different classes. The poor receive twenty ounces of bread daily, with four ounces of meat, a bottle of wine, and fruit; and macaroni twice a week. The half boarders, who pay six ducats a month, get two dishes a day; the whole boarders pay double, and get three dishes, and on Sundays and holidays, four.

The principle on which the establishment is conducted is to effect cures by gentleness, combined with strict military discipline. For this reason, the lunatics wear a uniform. Those who pay are distinguished from the poor by coats, the latter wearing jackets; priests have a cross on the breast.

The colour of the cross and of the coat-collar varies according to the species of lunacy; red for the furious, yellow for monomaniacs, white for the fatuous (*stupidi*), green for the epileptic, and blue for the dementes.

All movements are conducted by beat of drum.

Of coercive means the only ones employed

are the strait waistcoat, the dark room, and the coercive bed fitted up with a night-stool and a contrivance for raising the head. There are douche and vapour baths besides the ordinary ones. Those lunatics whose condition permits it, may go out three times a week.

Sicily. Palermo.—The medical and benevolent institutions are here as difficult to be seen as they are easy of access at Naples.

I was not able to get into the *Albergo dei Poveri*, or the *Conservatorio di Spirito Santo*. The Civil Hospital contains 608 beds; Longo is the Director, and the Marchese di S. Giorgio the Administrator. The division for girls of the town, who are also examined here, is not well arranged; it consists of 230 beds, in four wards. They have two ounces of meat and wine daily.

In the *Collegio militare*, or *della Benificenza*, foundlings are made into soldiers.

In front of the town is situated the new madhouse, founded at the instance of Pietro Pisani, who had also written a book on the subject, the *Guida dei Forestieri, per la Real Casa dei Matti, Palermo 1835*. (The Foreigner's Guide to the Royal Lunatic Asylum.) It contained 58 women and 44 men. For the former there are 120 cells, in two stories, those for the unquiet below, and those for the furious above, arranged around a court which contains an enclosed fountain. The men have twenty cells for the furious round a small court; the quieter ones are kept in the building, where there are also rooms for the patients who pay, at the rate of twelve ducats a month. There is a parlour for each sex, where they can converse, under inspection, with relations and friends. One apartment is devoted to weaving. The baths are very beautiful, and the whole building arranged with much luxury. For the amusement of the lunatics the gardens are furnished with allegories [allegorical groups?], caricatures, grottos, temples, and various games, partly constructed by the lunatics themselves. These interested my guide so much that through them I obtained no information on more important points. The coercive instruments used are the strait waistcoat, the dark room, and the hammock. Connected with the institution is a small, but very interesting, collection of the skulls of insane persons. Changes of fortune, and violent mental emotions, during the prevalence of the cholera in 1837, were abundant sources of madness. The botanic garden, under the direction of Professor Tinco, situated near Flora's Walk, is magnificent. The amphitheatre for lectures is built in an ornate Doric style, and decorated with statues of Æsculapius, Hygiea, Flora, Pomona, Ceres, and Abundance. A statue of Paris represented as a herdsman fronts the green-house.

The round basin for water plants is crossed by a complete net-work of small stone bridges, situated partly in concentric circles, partly in their radii, so that it is easy to reach any single plant.

Prince Butera's garden is also botanically interesting; the gardener is a German named Schott.

Besides artistical and antiquarian collections, the University contains the anatomical theatre, and a small pathological cabinet, particularly interesting for its specimens of intra-uterine life. The best known among the Professors is Foderà, the physiologist, who formerly lived at Paris, but was born here.

[To be continued.]

QUANTITY OF CARBON USED
IN FOOD.

THE quantity of carbon consumed, in the form of food, by different individuals, is subject to considerable variation. It is well known that some persons are notorious

among their friends and acquaintances for being great feeders,—while others are commonly known as small eaters. The difference is still greater when we compare the eating powers of the inhabitants of different countries. Whether this depends, as some phrenologists assert, on the unequal development of a particular part of the brain (which they call the *organ of alimentiveness*) I shall not stop to inquire: it being sufficient for the present purpose that the existence of inequalities of appetites among different individuals is generally recognised.

Liebig estimates the amount of carbon daily consumed at $15\frac{3}{10}$ oz. avoirdupois [$13\frac{9}{10}$ oz. Hessian] exclusive of that consumed in the form of green vegetables, &c. His statement is based on observations made on the average daily consumption of food, by from 27 to 30 soldiers, of the Body Guard of the Grand Duke of Hesse Darmstadt, in barracks, for a month, or by 855 men for one day. I have drawn up the following table from his statements, and converted the Hessian weights into avoirdupois weights.

Kinds of Food.	Avoirdupois weight of Food.			Avoirdupois weight of Carbon.		
	lbs.	oz.	grs.	lbs.	oz.	grs.
Ordinary meat containing $\frac{1}{2}$ of fat and cellular tissue	306	4	186	80	14	210
Fat or Lard	3	13	$304\frac{1}{2}$	3	1	$156\frac{1}{10}$
Lentils	3	10	412	}	11	10
Peas	12	12	161			
Beans	15	0	76			
Potatoes	1093	2	357	133	5	$374\frac{2}{10}$
Bread	1923	9	$214\frac{1}{2}$	589	11	$50\frac{1}{2}$
Total for 855 men for one day	3358	5	398	818	11	47
Average for one man for one day . . .	3	14	$370\frac{1}{2}$	0	15	140

In addition to the above, the 85 men consumed,

	lbs.	oz.	grs.
Of green vegetables (cabbages, greens, turnips, &c.)	189	7	$401\frac{1}{2}$
Of sourkroust	110	2	325
Of onions, leeks, celery, &c.	26	11	$203\frac{1}{2}$

Total for 855 men for 1 day	326	6	55
Average for 1 man for 1 day	0	6	47

It also appears, from an approximate report of the serjeant-major, that each soldier consumed daily, on an average, out of the barracks, the following quantities of other foods:

Sausages $3\frac{3}{10}$ oz.	} Avoirdupois weight.
Butter . . $\frac{3}{4}$ oz. & $33\frac{1}{3}$ grs.	
Beer . . . $\frac{1}{2}$ pint	
Bready . . $\frac{1}{10}$ pint	

So that we may fairly assume, that each of these soldiers consumed daily about one

pound (avoirdupois) of carbon. Now if we suppose that while under experiment he neither gained nor lost in weight, what, it may be asked, became of the carbon thus taken in the form of food?

I shall assume, with Liebig, that the carbon of the green vegetables, sourkroust, and onions, was equal to that of the feces and the urine, and shall exclude from our calculation the carbon of the small quantity of food (sausages, butter, beer, and brandy) taken in the alehouse. We have, therefore, to account for the disposal of 15 ozs. 140 grs. avoirdupois (= $6702\frac{1}{2}$ grs. troy) of carbon; nearly the whole of which quantity must have been thrown out of the system by the lungs and the skin in the form of carbonic acid.

Now $6702\frac{1}{2}$ grs. troy of carbon require 17,840 grs. of oxygen gas to yield $24,542\frac{1}{2}$ grains of carbonic acid; and it is remarkable that Menzies estimated the quantity of

oxygen consumed in respiration by a man in 24 hours at 17,625 grs.

Consumption of oxygen in 24 hours.

Cubic Inches. Grs.

Lavoisier and

Seguin . . . 46037 or 15661 (French)

Menzies . . . 51480 or 17625

Davy . . . 45504 or 15751

Allen and Pepys 39600 or 13464

If it be objected that the estimate of Menzies is too high, it may be replied, that the amount of food consumed by the Darmstadt soldiers was perhaps above the average. Each of these is calculated to have eaten $35\frac{23}{100}$ ozs. avoirdupois [32 ozs. Hessian] of bread, and about 6 ozs. avoirdupois, of meat (besides the 3 ozs. Hessian, of sausage) daily. Now in the dietary of the Stepney Union (which, I am assured, is considered to be a very good dietary for paupers) the Poor-Law Commissioners allow only 14 ozs. of bread, and rather more than $2\frac{1}{2}$ ozs. of meat, as the daily supply.

Moreover, the consumption of food, and consequently of carbon, by females, is considerably less than that by the Darmstadt soldiers.—*Dr. Pereira*, in the *Pharmaceutical Journal*.

ANATOMICAL AND PHYSIOLOGICAL OBSERVATIONS ON THE CORDA TYMPANI.

M. GUARINI has lately published a monograph containing some experiments and observations on the functions of this nerve, which has already occupied so large a share of the attention of physiologists.

The author adopts the opinion that the corda tympani is not derived from the cranial branch of the vidian nerve, but takes its origin from the facial. He concludes, therefore, that it is, like the facial, a motor nerve. In the second place, he shows by dissection that the corda tympani is distributed principally to the fibres of the lingual muscle, and he thinks that it communicates a motor power to them.

To verify the justice of this opinion, he performed experiments on animals; striking them on the head, and then quickly making a section of the tongue and the inferior maxillary bone in the mesial line. After waiting till the spasms which affected the muscles had ceased, he implanted one of the needles of a small galvanic pile in the anterior part of the tongue, and connected the other with the nerve whose function he desired to ascertain. He found that, when the hypo-glossal nerve was galvanized, the tongue was moved forwards and backwards,

upwards and downwards, with such rapidity, that the whole organ appeared convulsed. At the same time the muscular fibres in the centre of the tongue remained unmoved.

When the needle was applied to the branch of the fifth pair of nerves no movements of the tongue ensued, nor when the glosso-pharyngeal nerve was touched.

If the facial nerve was galvanized the tongue was carried upwards and backwards, then downwards, then again upwards, at the same time undergoing a sort of vermicular movement from the action of the lingualis muscle; the movement upwards and backwards being due to the contraction of the stylo-glossus, the upper part of which receives branches from the facial nerve by means of the corda tympani.

These experiments were repeated several times with perfect success by M. Guarini, in the presence of his colleagues. It being doubtful how far the vermicular motion of the tongue might be attributed to the action of the stylo-glossi muscles, these muscles, together with the stylo-pharyngei and digastrici, and the hypoglossal nerves, were divided, the head having been separated from the body, and the corda tympani and lingualis muscles left entire. The facial nerve being then galvanized, the tongue was no longer carried backwards, but the vermicular movement continued unimpaired.

The physiological conclusions which the author draws from these experiments are, that the hypoglossal is not the only motor nerve of the tongue, and he considers that by its influence upon the lingualis muscle the corda tympani is subservient to the articulation of sound.

The suggestion that the corda tympani is a motor nerve and derived from the facial is by no means new, though the part to which its influence is supplied has been a subject of much discussion. The above experiments seem to have been conducted with much care, but they are of such a nature as to require repetition in other hands before we can consider the inferences drawn from them to be established.

ON THE SWALLOWING OF SPONGE BY A HORSE.

By MR. GEORGE RICKWORD, Retford.

AN extraordinary case has lately come under my observation of a horse swallowing a piece of new sponge, and which caused not the slightest inconvenience to him, although he did not pass it until nine days afterwards. The case is as follows:—

Thos. Chas. Higgins, Esq. of Survey House, in this county, purchased a six-year-old horse of a dealer in the neighbourhood.

Not being wanted for immediate use, he was turned into a paddock, where he remained a week. At the expiration of that time he was brought up for the purpose of getting through his physic, and was placed in a loose box away from the stables, and put upon a bran-mash diet. Upon the groom going into the box on the following morning, he remarked that there was a peculiar offensive smell, resembling the effluvia from dead rats; and upon removing the faeces he discovered a piece of sponge, the size of an egg, and which explained at once the cause of the stench.

In order to convince himself that the horse had not taken it during the time he was in the box, he examined his stock, and found that he had not lost any; and he is quite positive that the horse must have swallowed it before he was in their possession, because no sponge had been afterwards used where he could possibly get at it. I have the sponge in my possession, and it appears to me to have been a new piece, and in my opinion has not in the slightest degree undergone the process of digestion.

I once met with the case of a horse swallowing a sponge, the particulars of which I sent to you. In that case not a particle was voided undigested, but the patient was ill to an alarming degree. There certainly was a difference with respect to their food: one had been kept upon hard meat for two or three years, and the other upon his natural diet, he having been at grass for some months.—*The Veterinarian*.

METHOD OF STOPPING BLEEDING FROM THE NOSE.

By DR. NEGRIER, of Angers.

THE following case, being one of those reported by the author, will show his method of proceeding.

April 1839.—A chimney-sweep, aged 14, had already lost 200 grammes [six ounces] of blood from the right nostril. The blood was still flowing very fast, the face was flushed, the eyes injected and weeping, the pulse full and soft, the skin warm. I had the boy placed with his head high; then, with the forefinger of the left hand, I compressed the nostril from which the blood was flowing. While doing this I made him lift up his right arm perpendicularly, telling him to keep it so for two minutes: the hæmorrhage had stopped in ten seconds.

M. Négrier relates three other cases, quite similar, where the epistaxis yielded with the same facility to the same remedy; and he might, he says, have considerably increased the number. The following fact induced him to try this plan.

"Some years ago," says M. Négrier, "I cut myself under the nose, while shaving. The blood flowed copiously from this petty wound, and I could not stop it, either with court plaster or by cauterising with the nitrate of silver. By chance, however, I lifted up both my arms at once to reach something, and I saw, to my great surprise, that the flow of blood, which was copious just before, immediately stopped. I lowered my arms, and the hæmorrhage began again; I again lifted them up, and again the blood immediately stopped. In this way I renewed and stopped the flow five or six times, in order to convince myself perfectly that the sudden raising of the arms was really the cause of the suspension of the hæmorrhage. Lastly, I kept my arms raised for one or two minutes; and during this period a plastic crust formed upon the cut, which put a final stop to the hæmorrhage."

M. Négrier has since remarked, that if the cut goes through the capillary vessels alone, the hæmorrhage is not stopped; for this effect it is necessary that the wound should contain some arterial branches of a greater calibre.

Our judicious contemporary, the *Gazette Médicale*, observes as follows upon this plan:—

We shall not undertake any explanation of this fact, which must first be verified; for although the authority of M. Négrier is sufficient to make us admit the mere fact, that is, the coincidence of the raising the arm and the cessation of the hæmorrhage, we cannot admit the influence attributed to the raising the arm, without fresh facts. Nor shall we quote the explanation given by M. Négrier, as it leaves much to be desired in every point of view.

STRUCTURE OF THE LUNGS.

In a paper lately read before the Academy of Sciences, M. Bourguery is of opinion that man and, in general, the mammalia, at the two extremities of their lives, approach the two classes of vertebrated animals which display the two extremes of aerial respiration. In fact, says the author, as adolescence approaches, the lungs, from year to year, present fresh sanguineous surfaces to the air, so that the breathing, by its development, if not by the form of its organs, more and more resembles the respiration of birds. In the old man, in proportion to the advance of decrepitude, the lungs are gradually decomposed into aerial caverns, which diminish the sanguineous surfaces in proportion; so that his respiration, both by its actual volume, and by the alterations of the structure of the organ in which it takes place, resembles that of reptiles.

SCHEME OF MEDICAL EDUCATION.

LET me now, sir, solicit your indulgence, while I submit, in a compressed and connected form, as an aggregate of the modifications I have suggested in our curriculum, a scheme of study and discipline, which I earnestly believe would provide for the public the largest number of efficient medical advisers. It comprises the following points:—

I. It would make the completion of eighteen years of age, and the attainment of certain preparatory knowledge, the indispensable conditions for a candidate's admissibility to the classes of technical study in a medical school.

His preliminary instruction should be tested by a pass-examination in the facts and philosophy of the Natural Sciences, to a certain defined extent; and should embrace an acquaintance with the principles of reasoning, with rudimentary mechanics, and with the definition and axioms of geometry, so far as these bear on the main subjects of the examination.

A voluntary competition for mathematical and for classical honours should also be invited, and the prize-man in each contest (if of sufficient merit) should be admitted to the medical school at a reduced entrance-fee (or gratuitously) with the title of mathematical or classical scholar.

II. A division of each school into two grades or departments, each having, as far as may be, its scope of study, its arrangement of subjects, and its mode of teaching, adapted to the more or less advanced knowledge of those trained in it.

(1.) The discipline of the junior department should extend through a period of fifteen months; and not only should frequency of formal examinations, and a general tone of indirect, or catechetical, teaching distinguish it, but the student's promotion should be made contingent on his proficiency in its curriculum. Descriptive anatomy (including dissections); elementary biology, as the study of life in the general history of its healthy and morbid manifestations, (elements of structural anatomy, physiology, and pathology); general therapeutics,—or so much of the science of medicine as is common to the physician and surgeon, either divested of speciality, or admitting it only for illustration,—with a classification of remedial agents, an account of their modes of operation and their usual employment in practice: these should be the chief studies of the period, and (during the summer which would close it) there might be added an attendance on the out-patient practice of a hospital or dispensary, in order to acquire,

under proper teaching, the method of conducting examinations, of studying symptoms, and of using the minor surgical appliances (*petite chirurgie*): to the same summer might likewise belong the study of practical pharmacy, and of chemical manipulations.

2. The second period of studentship, being that of discipline for professional practice, should be cultivated in this view with strict and exclusive care: during its earlier half, three or four hours in the middle of each day should be given to visiting the wards of an hospital, and to attending the clinical lectures, and the demonstrations of morbid anatomy, which illustrate its practice; and the anatomical studies of the forenoon should take, as much as possible, the form of surgical anatomy. Thus the systematic lectures on the three branches of practice would fall (as indeed they ought to fall, for the student can ill afford at this period to exhaust daylight in the lecture-room) to the evening; but I am inclined to believe that if clinical teaching were constant and efficient, (as in some foreign schools, where it resolves itself into a familiar commentary on each day's visit) it would form an advantageous substitute for a considerable portion of the systematic courses.

During its later months, the same general plan should be followed, with a care to excite the student's personal interest in practice, and to prepare him for future responsibility; the opportunity of attending cases, under proper direction, should be afforded him, and a registry of them required at his hands. Closer observation of particular classes of disease (surgical and medical specialities) should be encouraged, and theses on them invited by the clinical teachers. Courses of lectures on the higher biology (with more abundant adduction of comparative anatomy and of embryology, than belonged to the earliest view of the same subject) and on forensic medicine and hygiene, would likewise engage the student's attention, and complete the circle of his regulated academic training.

III. It should be a leading object, and a characteristic feature, in the whole scheme of instruction, to superintend the pupil's course; not only to inform him, but to ascertain his progress; not only to sketch his route, but to direct its detail. Thus, when his term of pupilage is accomplished, the teachers of his school can certify for him that he "has completed to their satisfaction the course of study and discipline which they recommend:" and I conceive that such credentials, from a well-constituted school, might with advantage be substituted for the more detailed, but far less comprehensive, certificates of the present system.

Thus far the education should be common to all branches of the profession, and in-

different to any special tendency : for, not till this cycle is accomplished, and a sound knowledge of general practice obtained, can any distinction of study be advised, with a view to the pupil's ulterior destination. Whether he propose confining his future practice to medicine, or to surgery, or to obstetrics,—thus far his culture and proficiency should be equal in all: whatever be the intended inclination of his further progress, thus far it should be impartial: let him first be an able and well-proportioned general practitioner, then specialize his studies; it is not by forswearing medical knowledge, but by accumulating surgical experience,—it is not by the absence of surgery, but by eminent skill in medicine, that a surgeon and a physician respectively distinguish themselves.—*Mr. Simon's Letter on Medical Education.*

ANTHRAX PRODUCED BY DISEASED MEAT.

DR. ODOARD TURCHETTI has published several cases of anthrax, caused by the ingestion of diseased meat. It appears that in 1841 an epidemic anthrax of the tongue raged to a great extent among oxen, and the flesh of one of those which had died of it was publicly sold at a low price in the market-place at Fucecchio. The meat did not present any appearance likely to create suspicion.

In some of those who partook thereof, small and very painful tubercles, surrounded with a red areola, or small whitish pustules with a purple or violet coloured circle, gradually increasing in size until they assumed the genuine characters of anthrax, showed themselves on the face, lips, neck, or arms, in the course of from twenty-four hours to three days. In almost all these cases, the slough was separated by an inflammatory process at the end of a week, leaving a more or less healthy ulcer, which was cicatrised speedily by emollient and detersive applications.

In the more severe cases the pustules ran together, and the anthraxal inflammation spread like erysipelas, accompanied by extensive livid swelling of the parts, and complicated with obstinate gastro-intestinal derangement. The sloughs in these cases did not separate for a fortnight, and left an unhealthy ulcer, which was induced to cicatrise with great difficulty. Two aged persons died from the disease.

Children under six years of age, elderly people, and persons of a weakly constitution, were those who were brought under the malignant influence of the poisonous food; persons in the enjoyment of full health and

strength generally escaped. The general symptoms produced were—diarrhoea, vomitings, meteorisation, borborygmi, anorexia, intense fever, subdelirium, prostration of strength, abdominal pains, insomnia, tendency to serous effusions, epistaxis, &c. The employment of emeto-cathartics and active antiphlogistics are said to have proved the most useful auxiliaries in the treatment of this form of anthrax. Convalescence was very protracted.

A young man, named Marraddi, eighteen years of age, twenty-eight hours after having partaken of this food, had an anthrax form on the upper eyelid of the left eye, which caused the mortification of the whole of that side of the face and neck, and part of the chest. The slough came away at the end of a fortnight, leaving an enormous ulceration, which suppurated abundantly and healed very slowly. The antiphlogistic plan of treatment was employed.—*Annali Universali di Medicina; and Provincial Med. Journ.*

ADIPOSE HERNIÆ OF THE ABDOMINAL WALLS.

M. DENONVILLIERS presented to the Académie de Médecine the abdominal parietes of a woman, in whom had occurred one of these adipose herniæ which are formed external to the peritoneum, and project through some aperture in the linea alba. In this case the fatty tumor presented the peculiarity, that it passed through the umbilical aperture in such a manner as to merit the appellation of an umbilical adipose hernia; and, sometimes projecting in front, at others receding behind the abdominal wall, it closely resembled a true hernia of intestine or epiplocele.

One circumstance in this case of peculiar interest was, that the patient was attacked with peritonitis, under which she sunk. She was not seen at the commencement of this attack, and it simulated the symptoms of strangulated hernia, in such a manner, as to induce many persons to believe that there actually existed a strangulated umbilical hernia. Examples are recorded in which this mistake has been carried to such a degree that the operation was performed. M. Denonvilliers was not, however, deceived by these appearances, and predicted before the death of the patient, the existence of some tumor of this nature, together with peritonitis. He could not reconcile the idea of a strangulated hernia with the persistence of symptoms. At least, the strangulation by the neck of the sac and the reduction *en masse* of the hernia and sac into the abdomen, together with the cause of strangulation, he thought to be very improbable in a

situation where the peritoneum is so closely connected with the abdominal walls.—*Séances de l'Académie de Médecine.*

[The latter observation is in accordance with the investigations of M. J. Cloquet upon this subject, who having accomplished the reduction *en masse* in twenty cases of hernia on the dead subject, states, that it is most easily effected in internal inguinal, then in crural, and lastly in external inguinal hernia, and that he has never succeeded in the umbilical herniæ of adults.—Tr.]

WOUND OF THE INTESTINES CURED BY NATURE.

By Dr. BEYER.

A CHILD, five years old, was apparently suffering from all the symptoms of marasmus to such a degree that the case seemed hopeless. The abdomen was very tense, and poultices were applied to relieve the pain seated in it. After this had been done for several days, a considerable quantity of yellow pus suddenly issued from the umbilicus, on which the abdomen immediately sank. In a few days, undigested and half-digested food appeared in the wound at the navel, which naturally lessened still more all hope of preserving the child. Nevertheless it recovered, after Nature had cured, first, the wound of the intestines, and then the one at the umbilicus; the child is now healthy and strong.—*Caspar's Wochenschrift*, and *Schmidt's Jahrbücher*.

COLD WATER TREATMENT.

To the Editor of the Medical Gazette.

SIR,

A WRITER in the last number of the British and Foreign Medical Review justly remarks, that "Priessnitz is original not in discovering this principle (the use of cold water) but in its application." * * * "By cold bathing alone, if we consult enthusiastic admirers of it, we shall learn that Priessnitz has been anticipated in the cure of gout, rheumatism, all kind of neuralgias, hysteria, and hypochondriasis, fevers, agnes, asthma, and a variety of chronic disorders."—(Brit. and For. Rev. pp. 434, 436.)

I would take the liberty of adding,—and in the treatment of acute inflammatory diseases: I allude particularly to pertussis in all its stages. I have employed cold bathing of the chest in this affection for years, and with very satisfactory results.

This mode of practice was made known to me by Dr. Hannay (Professor of Medicine, Anderson's University, Glasgow) in a course of lectures delivered some ten or twelve years since. I have reason to believe that this gentleman still continues to prac-

tise and advocate this plan of treatment as the most speedy and safe means that has been hitherto recommended in the management of pertussis.—I am, sir,

Your obedient servant,

MEDICUS.

A TABLE OF MORTALITY FOR THE METROPOLIS,

Shewing the number of deaths from all causes registered in the week ending Saturday, October 8, 1842.

CLINICAL LECTURES,

Delivered at St. Thomas's Hospital,

By FREDERICK TYRRELL, Esq.

Surgeon, and Lecturer on Clinical Surgery, at St. Thomas's Hospital School.

INTRODUCTORY LECTURE.

As one of the surgeons of this hospital, the time has arrived when I should commence my duties in the department of clinical instruction. It was with no inconsiderable regret that I felt compelled, by the obligations of declining health, to confine myself to this less active, but you will hereafter find not less important, sphere of medical education, and to withdraw myself from the lectureship on surgery, which I have long had the honour and the pleasure to hold in this school. But if this retirement, with its attendant circumstances, tend only to raise within me feelings of regret, no ordinary consolation is given me by the recollection that, in the capacity of clinical teacher, opportunities of ample character will be still left me, to exert myself in the service, and to further the prospects of those who may seek, within the walls of this hospital, the materials by which, hereafter, to render service in the cause either of science or humanity. The inculcation, derived from a treasury of long experience, which it is important to impress upon your minds at the onset of your studies, respects the striking fact that the science of medicine and surgery is essentially one of personal-practical observation. In seeking acquaintance with the varied facts and realities on which its superstructure is reared, it would be an error of the most fatal tendency to anticipate continued, certain, and invariable guidance from any general laws, although they may be dignified under the title of the "fundamental principles of the science." These laws do not participate in the definiteness and ex-

actitude of those which constitute the bases, and regulate the demonstrations, of astronomical, chemical, mechanical, and other departments of physical science. Until, therefore, the principles on which the practitioner conducts the treatment of disease be exalted to the certitude of invariable laws, the purity of science would be violated if a place were claimed for them under its denomination. Let not these remarks, however, shake your faith in the resources and capabilities of our profession. The experience of observant men, the sagacity and genius of the numerous philosophers whose names render memorable the annals of medicine and surgery, have wrought out, and masterly moulded into available forms, from the chaos of recorded facts, and cases, and experiments, a code of useful and practical rules, which are to the student in our profession what the laws of matter are to the chemist, or the axioms of geometry to the astronomer, or the theorems of algebra to the theoretical mechanic. It becomes your special duty, therefore, to familiarise yourselves with these rules, in order that in the future management of disease you may interpret facts, establish diagnoses, and sketch the scheme of treatment, in accordance with their spirit.

Before commencing the study of disease and its treatment, it is essential that the pupil should possess at least a general, if not an accurate, knowledge of anatomy, physiology, chemistry, materia medica, and botany, which may be termed the elementary departments of medical science: we presume, therefore, that those who attend to our practical instructions possess such information, or they will find our observations of little value.

The right method for the prosecution of a practical course of study resolves itself into two divisions, of which one consists in the careful perusal of books and attendance upon lectures, while the other requires the positive observation of disease, and the per-

sonal examination of cases—both leading to the same important end, the knowledge of elementary principles. These two methods of attaining the same ultimate objects are, notwithstanding, radically different; for in character and practical value, the information obtained in the two cases is actually dissimilar, although known under the same name. For illustration, let it be supposed that a student learns in books that the signs or conditions of disease *a*, *b*, *c*, and *d*, if they present and combine in certain relative proportions of intensity, would produce a result which may be called *f*, or the compound of the signs; it is quite easy for the student to understand that if the same combination of these signs, under a precise similarity of circumstances, occur upon a second occasion, the same resultant would arise: *calor*, *rubor*, *tumor*, *et dolor*, if they are exhibited simultaneously by any given part, may be regarded, in all instances, as certain indications of a fifth condition, which is known under the term *inflammation*. It is evident, then, that such a proposition as this is purely abstract in its character, and the knowledge obtained is essentially theoretical. But suppose that he acquaint himself further with the sub-signs of *a*, *b*, *c*, and *d*, that he make these signs objects of intimacy to his senses; so that if *a*, or *b*, or *c*, or *d*, were afterwards to be met with either separately and singly, or in different proportional relation to the others, its value as a manifestation of disease would be at once and correctly estimated. But all the deviation from the unit or principle from which we have started could only be determined and recognised by the thoroughly practical student; by him who knows, to speak algebraically, not only the respective values of these several signs, but also the properties or characters by which each may be distinguished. Well, suppose that he informs the "book student," who is as well aware as himself that the concurrence of the signs *a*, *b*, *c*, and *d*, make up inflammation as their necessary product or sum, that in a second case, the sign *a*, or the *calor*, is almost entirely wanting, as well as *d*, or *rubor*, he would be able very accurately to draw the negative inference, that, at all events, it was not one of *inflammation*. But this would go but a short distance in the path of analysis: his difficulties would begin to increase in his attempts to extend his acquaintance with the case. But from the same point of apparent perplexity the course of the truly practical and observant student would appear at once clear and definite: he would promptly proceed to analyse the characters of the two remaining symptoms, *tumor* *et dolor*: he would ascertain with exactitude what sort of swelling it was, what its anatomical dependencies, what the pecu-

liarities of the pain—was it lancinating, throbbing, continued or intermittent, deep-seated or superficial: thus he would work out the nature, as well as seat, of the disease, determine its malignity or non-malignity, whether it had its origin in the osseous or soft structures of the part. Gentlemen, learn from the picture of this hypothetical, but frequently-occurring case, which I have drawn to your contemplation, the all-important fact, that the desirable qualities of *facility* and *accuracy* in the formation of diagnosis, soundness of judgment in the management of disease, can be attained only by a persevering and well-directed course of bed-side observations—learn from the details of this imaginary case, to estimate rightly the value of clinical instruction. It should never be forgotten that implicit dependence cannot be placed upon the guidance of general principles. In this respect the bases of medicine and surgery are still unstable and insecure; the conclusions of the diagnostician, therefore, cannot as yet attain the standard of certainty and infallible precision. There is, notwithstanding, a system or plan of investigation recognised as the right pathway for extending the boundaries of medical science, a plan which the greatest physicians have pursued with success; it consists in following out each fatal case through the full details of post-mortem examination; let the evidence of this last practicable process correct or verify, improve or modify, the diagnoses previously pronounced. Thus the mind will be furnished with valuable and important material for the formation of a sounder diagnosis, or a more accurate judgment, on any future and similar occasion. It is remarkable that students, at all periods, have under-estimated the importance of that species of information obtainable by personal attendance at the dead-house. This consolidates and renders permanent the knowledge accumulated in the wards. In this, as well as in all large hospitals, persons of competent learning in the principles of disease, and adequate acquaintance with general pathology, are always appointed to conduct the inspection of the dead, in order that the inquisitive student may have every facility and assistance afforded him in the solution of difficulties, and removal of obstacles, by which his progress may be retarded. Let me, then, express my sincere hopes that you will desert no case, however common its character, at the dissolution of the patient; "the last scene of all" should never fail to excite within you a philosophic anxiety to test the accuracy of the opinions which the attending physician or surgeon may have delivered during his walks round the ward. This is the course by which labour, industry, and talent, have amassed the folios of facts and cases out of which the principles that

rationalise the practice of our profession have eventually been developed. Let me present you with this important lesson in a direct, and probably more impressive form, by narrating the circumstances of a case which, many years since, occurred to the late Dr. Chomely, of Guy's Hospital. A young woman was brought under his care at the hospital. Her chief complaint was that of severe and continued headache. The state of the bowels and stomach, although not considerably deranged, induced Dr. Chomely to conceive that the affection of the head was sympathetic with the disorder of the stomach and bowels: he accordingly addressed the treatment to the relief of these parts. By the advice of his colleagues, however, who regarded this striking symptom of pain as consequent upon disease in the head itself, the temporal artery was opened, and blood removed to fainting. As he expected, this step brought with it no relief to the head. In consequence of the slipping off of the bandage, however, during the night, a considerable quantity more of blood was lost; so that the patient was reduced to a condition of extreme weakness and exsanguined appearance, the tongue and prolabia being perfectly white. On his visit in the morning, Dr. Chomely found that the headache was entirely gone, and he began to think that his original opinion as to the nature of the case was incorrect; but before reaction was fully established, the headache returned with unsubdued severity, and within a comparatively short period the patient sunk from pure exhaustion. Dr. Chomely, with an ardour of inquiry which eminently and long distinguished his labours in the cause of science, as unwilling to confide in as to relinquish his first idea of its character, sought, in the examination of the body, the settlement of all doubts, and the correction of all errors. It was found that an extensive organic disease of the stomach existed, presenting the marks of having passed through a slow and long period of growth. In the brain no evidences of disease were discovered. It was thus, by industriously following out the case to its last stage, that a valuable proof was ultimately elicited of the accuracy of Dr. Chomely's original opinion, and of the error committed by his colleagues. The history of a case so complete as this teems with instructive details; yet the numerous advantages afforded within the wards of this hospital, the regularity with which the post-mortem examinations are conducted, the facilities offered in the plan of clinical teaching now established in this great school, throw open to you all abundant opportunities for filling your case-books with cases as complete in history, and remarkable in interest, as that which I have pictured to you from the practice of Dr. Chomely. Let me

assure you, by the experience of thirty years, that facts so accumulated will afford you the best and safest pilotage under the perplexities of actual practice.

It is the opportunity of satisfying yourselves in all fatal cases of doubtful diagnosis that renders attendance upon in-door patients so peculiarly valuable and instructive, and which allows the teacher such superior advantages in his efforts to instruct. Each student has the power to investigate, by himself, the characters of the disease; so that, in afterwards collecting to listen to a clinical lecture upon the case, all are furnished with a sufficient knowledge of its history to interpret rightly, and appreciate, the observations of the surgeon or physician. This plan has always appeared to me infinitely preferable to that of making, at the bed-side of the patient, before the eye, and in the hearing of the sufferer, remarks which may aggravate his distress and sink his spirits. Humanity sets her interdict against such a practice; and science by no means requires it.

In reference to the establishment of *correct diagnosis*, there are several cautionary points to which I feel anxious to direct your best attention. There are two modes for obtaining the necessary information on which, in every instance, to found the diagnosis, of which one may be called the *subjective*, and the other the *objective*. These are two distinct methods of conducting the inquiry; and they are designed to elicit two different descriptions of evidence.

Subjective evidence is that which the patient himself deposes. It is the account of his own case which he himself presents; consequently each symptom is measured by his own imagination, and coloured by his fears and timidity, magnified by his fears, or diminished by his unwillingness to believe that a severe attack is approaching. The picture which he draws of his case may be exact and coherent in its details, or it may be artificial and irreconcilable with that to which the surgeon conceives it to belong, from the parts or part affected. It is this absence of consecutiveness in the story, that betrays the counterfeit character of cases which are not unfrequently brought under our observation. But the prompt detection of such attempts at imposition supposes, on the part of the medical man, an available and comprehensive acquaintance with the minute history of every *shade* and *form* which every disease, at all events the recognised affections incident to the part, can assume. Allow me in passing, gentlemen, to awaken your pride of heart and independence of mind to the quagmire of mortification into which a surgeon is reduced when thus misguided by the plausible fabrications of his patient. In your own cases let me entreat you to prevent the possi-

bility of occurrences so stigmatising to reputation as that presented by the following case.

I was called to see a young lady who had been confined to bed, in a recumbent posture, for more than five months; and was informed by her medical attendant that the lady suffered, and was still suffering, from severe disease of the spine at the upper dorsal region; that she had undergone much pain by leeching, cupping, blisters, moxas, &c., and that at present she had two issues at the sides of the spine over the seat of the disease: this plan of treatment had been adopted by the advice of some experienced persons, who had formed the diagnosis above expressed. Careful inquiry and examination soon brought me to the conclusion that there was not any positive disease of the spine, but that the case was one in which, under a highly developed hysterical diathesis, severe and continued local pains had occurred independent of any local morbid action, tending to organic mischief or change. I therefore directed a nutritious diet, exposure to pure air, regulation of secretions, and the use of steel and foetid gum, with the relief from all kinds of local irritation, and in less than five weeks had the pleasure of seeing the patient walking about free from pain, and no longer exhibiting any symptoms of disease of spine.

Objective evidence elicited in the examination of patients, on the contrary, assumes such a precision of character as to make it to the physician what the circumstantial evidence of an eye-witness is to the Judge in a court of law. It is that species of substantive information which is obtained in a given case by direct observation. A patient complains of extreme difficulty in breathing, and of an aggravation of the oppression if he lies on the side opposite to that affected; thus offering a *subjective* account of his case. The physician now, by means of the stethoscope, determines the presence of a fluid in the pleural cavity, a want of resonance on percussion, a bronchophonic resonance in the voice—phenomena which are made direct *objects* of recognition by the senses. A person applies at the surgery for admission to the hospital, on the plea that he has dislocated his shoulder: his arm is removed a little from the side, he complains of some difficulty in approximating it to the body, but not of that severe pain which in the case of the most common dislocation is caused by the pressure of the head of the bone against the brachial plexus, when the arm is brought into parallelism with the side. The suspicion of the surgeon is excited by certain *discrepant* points in the tenor of *this subjective* evidence. He accordingly proceeds to develop the *objective*. The man is undressed, and the shoulder exposed; it is at once observed not to have lost its ordinary contour; the arm

is not elongated; there is no discoverable vacuity underneath the acromion; there is no globular tumor corresponding with the head of the humerus, either in the axilla or dorsum scapulae, or under the clavicle. The surgeon, therefore, from the evidence of facts thus *objectively* gathered, arrives at a conclusion very opposite to that which the subjective narrative would have led him to form. Such a case is satisfactory in illustration of the superior value which attaches to all descriptions of objective evidence, especially when elicited with judgment and intelligence. There are, however, many instances of disease in which the subjective story, related with clearness and precision, most accurately defines the genuine characteristics of a disease. Imagine a case of hydrocele. The patient states that some months since he observed the scrotum to have become slightly enlarged at its lower part, that the swelling acquired an increase of dimensions by enlarging from below upwards, that the swelling was attended with little inconvenience or pain—a picture is thus drawn which at once impresses the mind of the surgeon in reference to the nature of the case; for the sake of greater precision of diagnosis, however, he proceeds to determine the existence of one objective symptom, whether, namely, the tumor is clear enough to transmit the light: this proved, he conjoins it with the narrative of the patient, and views the case as one of hydrocele. In conclusion, then, I may repeat, that the process of inquiry which a surgeon or physician institutes as preliminary to the formation of his diagnosis, should always be conducted with clear and intelligent reference to the two departments of evidence of which I have here endeavoured to convey to you some conception.

In the prosecution of inquiry with a view to accurate diagnosis, there is a question of fundamental import yet to be discussed:—has this affection any dependence upon the general system or constitution, or is it wholly or exclusively confined to the affected part, is a question of considerable consequence to the welfare of the patient in a great variety of cases. Suppose two cases somewhat similar in outward characters, but radically different as regards their pathological conditions—one intimately dependent upon, and regulated by, the state of the general system—the other entirely local: and suppose the same plan of treatment, founded upon the erroneous idea that they were both exclusively local, or both exclusively constitutional, to be pursued. It requires but the plain application of common sense to perceive that, under such a course, while one case would improve, the other would suffer aggravation and injury. Two cases, for example, of ulcer of the leg may come under observation and treatment at

the same time, presenting very closely the same conditions of pain, redness, secretion, swelling, &c., such as would indicate an excess of action; yet in one such an appearance might depend entirely on circumstances influencing the part directly, and would therefore be termed *local*; whilst the same condition in the other case might be no less caused by some disturbed state of the general circulation, or important error in the general functions of the system. It is scarcely required to state, that a course of treatment having reference only to the local, or conversely, to the constitutional, condition, would be as much calculated to injure the one case as to benefit the other.

In forming his diagnosis, the pupil should, as far as possible, endeavour to do so by himself, and subsequently follow out the cases when examined and prescribed for by the

physician or surgeon, and if he finds himself in error, he should seek explanation from the physician or surgeon: thus the knowledge obtained will make deep impression.

Commonly, the pupil is satisfied by following the physician or surgeon, and adopting, without further inquiry, his statements or opinions: the information thus obtained is seldom retained, because it makes little impression at the time. Recollect that our science is still very imperfect, and that the most experienced is liable to err; do not, therefore, rest satisfied until you yourselves are convinced.

I have still a few observations which I consider important to offer to you before I commence my clinical lectures; but I must defer these until I have the pleasure of meeting you again.

REPORT OF THE COMMITTEE ON HOSPITAL STATISTICS.

THE present Report, which has been drawn up by a Committee of the Council of the Statistical Society of London, appointed in December, 1840, "to consider the best means of obtaining periodical enumerations of the patients in the London Hospitals," has been approved and adopted by the Council, and has been ordered to be published in the Society's journal, and to be printed for circulation amongst the supporters and authorities of the various medi-

cal charities of the metropolis. The objects of the Council in appointing the Committee will be sufficiently apparent after a perusal of the Report itself. The Committee is still engaged in inquiries connected with the vital statistics of the hospitals, and will be happy to receive information or suggestions from gentlemen interested in such matters, in furtherance of the purposes of their appointment.

Population of the Hospitals.—The metropolis contains ten general hospitals, besides the fever hospital, the small-pox hosp. the Lock hospital, the hospital for seamen, several lying-in hospitals, and lunatic asylums.

A Return of the Number of Patients in the undermentioned London Hospitals, and of the other Persons belonging to the respective Establishments, or resident on the night of the 6-7th June, (From the return made by the Officers to the Census Commissioners.)

Name of Hospital.	Number of Patients, June 7, 1841.			Number of Persons employed in the Establishment, or Resident on June 7, 1841.			Grand Total.	Deaths in 1839.

Total . . .	1482	1081	2563	170	605	775	3338	2231

The lying-in hospitals, Lock hospital, and lunatic asylums, have not been included in the present inquiry.

The population of the hospitals is shown in the preceding table, for the particulars of which we are indebted to the kindness of the Census Commissioners. It must be borne in mind, that the number of patients in individual hospitals fluctuates, and that it is probably not quite so great in summer, when the census was taken, as in winter. With these qualifications the table represents pretty accurately the distribution of patients, and the proportion of males and females in the metropolitan hospitals.

The Dreadnought contained 168 male patients; the hospitals for fever and small-pox (which were not epidemic in June 1841) 29 males, 25 females; the 10 general hospitals, 1,285 males, and 1,056 females.

As a preliminary step, it appeared to your Committee desirable to obtain an enumeration of all the patients in the London hospitals. A circular was accordingly addressed to some of the medical officers who had evinced an interest in statistics; and blank forms were forwarded to all who expressed themselves favourable to the objects of the inquiry. Returns were finally obtained from the Westminster, Middlesex, Charing-Cross, King's College, University College, London, and Dreadnought, hospitals, for

which we are indebted to Dr. Watson, Dr. Burne, Dr. Golding, Dr. Guy, Dr. Walshe, T. Blizard Curling, Esq., and G. Busk, Esq.: who either performed the enumerations themselves, or selected intelligent gentlemen, quite competent to the task.

We were not fortunate enough to procure returns for the first enumeration from St. George's, Bartholomew's, St. Thomas's, or Guy's hospitals, but from the information which we have received, we have every reason to believe that the medical officers and governors of the two former hospitals will contribute to the next inquiry, and we hope that the governors and the medical officers of Guy's and St. Thomas's may be induced to follow their example.

The 7 hospitals from which we have obtained returns, contained 1,127 in-patients, on June 1st, 1842; and 1,214 in-patients in the first week of January, 1842. The increase (7·7 per cent.) may be ascribed to the winter season.

In the 6 general hospitals (the Dreadnought being included), the proportion of males was 57 in 100 patients.

The following was the form of schedule employed in the enumeration; and it will be evident that the number of important heads which it embraces may be classified in a great variety of ways, each of which would furnish important information*.

Name.	Sex. M. or F.	Married, Single, or Widowed.	Occupation.	Age.	Disease.	How long ill before Admission.	How long in Hospital.

The time has not yet come for the final arrangement of the facts, or for the deduction of general results; but in the present stage, we hope to be able to indicate the utility of the inquiry, its general scope, and the important objects which it aims at accomplishing.

Distribution of Sex, Age, and Disease, with duration and results.—For the present we shall omit the Dreadnought, as that hospital is exclusively devoted to the reception of sailors.

The returns show (1.) the number of persons in the hospitals of different occupations; (2.) the number of each sex suffering from the several diseases at different ages; (3.) the period of the several diseases in which patients are admitted; and (4.) the time that they remain under treatment.

The table A. shows the ages of the patients, and their diseases; without distinguishing the sexes, which are, however, separated in the accompanying abstracts. In making these illustrative extracts, the same forms have been employed as are in use for classifying the causes of death at the General Register Office. In the ultimate arrangement, several other diseases, such as those of the skin, will require separate heads.

We subjoin some of the more common diseases, comprising 697 cases, which it will be seen are proportions of the total number of cases of all kinds (1,013) in the abstracts. As few children are admitted into the hospitals, all under the age of 15 are omitted.

* A copy of the form for enumeration, as finally determined upon, will be printed in a future number of the Society's Journal.

Ages of the Patients suffering from some of the more Common Diseases, in the London Hospitals, January 1812.

* Age of one person not stated.

General Remark.—The constant number of patients afflicted with any given disease, depends upon its duration, as well as upon the numbers attacked; so that where a disease is twice as long as another, although the same number were attacked, twice as many may be expected to be in hospital. Hence the proportion of cases of different diseases in hospital, and the proportion of cases admitted, will differ in the ratio of the average term of residence. Generally speaking, the proportion of the various cases in hospitals will agree with those of equal severity in the adult population out of doors; but there are exceptions; the diseases incident to childbirth, typhus, and consumption, are rarely treated in the general hospitals, while fractures, wounds, urinary, and a few other diseases, are collected in excess.

An abstract of the deaths, and causes of death, at different ages, in the London Hospitals (1839), was given in the Appendix to the Registrar-General's last report; of which we shall avail ourselves, to show the nature of a few of the results deducible from mere enumerations, and the registers of the causes of death. The abstracts of deaths was derived from all the hospitals, comprising 2½ times as many patients as were enumerated

for us; we shall therefore multiply our facts by 2.5, which will enable us to use them as illustrations. And we may state once for all, that they are to be considered nothing more.

Illustrations.—1. A comparison of the annual number of deaths from each disease, with the average number labouring under the same disease, shows the mortality in a given time (a year), in the various diseases. Thus if there were 95 consumptive persons on an average in the hospitals, 342 died in the year; 360 per cent. in 36½ days, or 1 per cent. daily. A physician who had on an average 100 consumptive patients under his care, in the advanced stage of the disease, may at this rate expect that one would die daily.

It appears that, in the general hospitals of the metropolis, 91 deaths occur annually for every 100 patients which they hold. An hospital which contains 110 patients yields 100 deaths. Let us suppose, for a moment, the patients labouring under consumption, pneumonia, &c. in separate hospitals, each containing 100 patients, the place of the dying being constantly filled up by new patients, then we shall have, according to the last column but one (Table B.), at the hos-

Further Examples—(TABLE B.)

3	Apoplexy	39	17	229	44
4	Injuries, and the effects of } Accidents	390	450	87	115
5	Bronchitis	88	111	79	126
6	Paralysis	42	55	76	131
7	Syphilis	13	110	12	846
	All Diseases.	2231	enumerated. 2462	91	110

pital, for consumption, 360 deaths; for pneumonia, 313 deaths; for apoplexy, 229 deaths; for accidents, 87 deaths; for bronchitis and catarrh, 79 deaths; for paralysis, 76 deaths; for syphilis, 12 deaths:—or, according to the last column (Table B.), 100 deaths would occur annually in an hospital for the consumptive, containing 28 occupied beds; in an hospital for accidents containing 115 beds; and in an hospital for syphilis containing 846 beds. The results are obtained with the same facility by the enumeration we propose, whether the diseases be treated in the same or in different hospitals.

An analysis of this kind can be made from five or ten enumerations. It will show, in different diseases, the relative *force* of mortality, which will no doubt be found to be regulated by a determined law.

2. The mortality, in a unit of time, at each age, from the different diseases, may be calculated from the enumeration of the patients, and the registered deaths.

We give the mortality from all causes as an example: the same method may be applied to each disease separately.

Ages.	Actual Numbers enumerated, multiplied by 2.5.	Deaths in One Year.	Annual Rate of Mortality per cent.
20—30	687	449	65
30—40	485	433	89
40—50	355	423	119
50—60	247	312	126
60—70	142	241	170

It has been shown by Mr. Edmonds, and others, that the mortality in the entire population, and in all cases of disease, increases about 34 per cent. (one-third) every 10 years of age after puberty. It appears also, from observations in Friendly Societies, that the sick time increases with age at the same rate;

when it would follow that the liability to an attack of sickness was the same at all ages from 15 to 60; that the duration of attacks increased 34 per cent. every 10 years; that the mortality of attacks increased 34 per cent. every 10 years; and consequently that the mortality in a unit of sick time (a week, for instance) from the same disease, was uniformly the same at all ages (or at least from 15 to 60, to which the observations have hitherto been confined). The enumerations will furnish the means of directly determining the latter point.

3. The tables B. C. show the number of patients *living at every stage* of the different diseases, (so far as it could be ascertained,) at the time the enumeration was made. If the numbers who *recovered and died at the same periods* were abstracted, the rates of mortality and recovery, at the several stages of all diseases, could be determined.

Our information is here deficient; we must refer for examples to other sources.

To render the information complete, a corresponding annual abstract should be made of all the *cases treated*, showing the numbers in each disease discharged, dead, cured, relieved, or otherwise, from all the hospitals.

The great desideratum, viz., the average and inevitable loss of life by each disease, as yet unknown, is obtainable only from such reports of hospitals, &c.—To ascertain the mortality and duration of diseases left to nature, has been considered by some persons a great desideratum. They want this datum, they say, as a starting point. They would determine the average duration, and the number of deaths in 1,000 cases of natural small-pox: they would then compare the results with the results of 1,000 cases treated with all the appliances of medical art; or, according to the various methods of treatment adopted by the medical schools. It is scarcely necessary to observe that the natural mortality and duration of diseases can never be supplied. The thing can never be even contemplated. No

one would dare to suggest that hundreds or thousands of patients should be deprived of the aid, solace, and counsels of medical art; which has been cultivated for centuries by a numerous profession, containing in its ranks many persons of the greatest scientific attainments, and a few men of the most consummate genius. We cannot ask patients to allow the stone to torment them, or to incur the natural risks of loss of blood, unreduced ruptures, broken bones, inflammations, in order to enable speculating sceptics to count how many of them will die.

Without some standard of comparison, however, medical science can make very little further progress. It will be impossible to determine accurately the relative value of different methods of treatment now in use; or of any new remedies and methods of treatment, which may be discovered. Medicine will always be open to unjust charges of inutility, and the public health will be the sport of fashion, the perilous innovations of empirics, and superficial theorists.

It is fortunate, under these circumstances, that the standard required will be furnished by the average mortality and duration of cases *under the present system of treatment*. In the aggregate results deduced from the thousands of cases treated in the hospitals, accidental irregularities will be destroyed; and the average rate of mortality and recovery in each disease, at each stage of disease, will be determined. With this standard any other class of similar cases, treated differently, may be compared. The collection and analysis of a few important, easily observable facts, to which the measures of number and time can be applied, will, it is evident, not interfere with, but will rather facilitate, individual research, or any special

and more extended inquiry undertaken by particular institutions.

The importance of applying the instruments and methods of inquiry which have enriched the exact sciences, to vital phenomena, is generally admitted; and the London hospitals will, it may naturally be expected, take the lead in this as well as in other departments of medicine. Should they act in an isolated manner, and independently of each other, or should they register the observations on a uniform system, and throw them into a common stock, to be arranged in the order which may appear, on due consideration, best calculated to yield the important results to which we have above adverted? The advantages of the latter proceeding, in a statistical point of view, are so obvious, that your committee have invited the medical officers to a conference, and have submitted to them the following propositions:—

(1.) To have authentic registers of cases kept in a form which is now under consideration.

(2.) The first registers to be commenced on January 1st, 1843, and to terminate on the 31st December. To comprise all the patients discharged during the year.

(3.) The first annual abstract to be made under the direction of a joint committee, named by the Council of the Statistical Society, the Boards and the medical officers of the hospital. For this purpose, copies of the registers to be sent, at the end of each quarter, half-year, or year, to the office of the Statistical Society, where it is proposed that the Committee shall meet.

(4.) The Statistical Society will supply the blank forms, for copying the registers of cases.

Example of the mode of filling up the proposed Return.

The medical officers who did your Committee the honour to meet them expressed themselves quite willing to promote these

important objects. The following resolution was passed.

“Resolved, that application, by letter,

be made to the Boards of the hospitals respectively, on the subject of the adoption of uniform methods of registering of cases, and that the sanction and support of the medical officers be requested to such applications; that a letter be drawn up and forwarded to the several Boards, pointing out the importance of the object in view by the Committee in making this application; and further, that a copy of the Committee's report be sent with each application."

It has been suggested that cases in the London hospitals will not present a fair average of the cases affecting the whole community. Your Committee admit the truth of this to the full extent. But after the example has been set in the London hospitals, your Committee are convinced that returns on the same plan could be procured from the provincial hospitals, the prisons, the poor-law unions, the friendly societies, and from private practitioners. This would open a wide field of comparison, and lay the foundation of improvements in the healing art, very much calculated to alleviate human suffering, and to prolong human life.

ON

DISEASES OF THE BRAIN.

By E. COPEMAN, M.R.C.S.

(For the *London Medical Gazette*.)

[Concluded from p. 116.]

CASE III.—Mr. S., a stout farmer, 80 years of age; joints of his fingers and toes filled with gouty concretions; was attacked on the evening of the 17th of May, 1842, with symptoms of apoplexy. I found him comatose, unable to articulate, almost unconscious of efforts made to rouse him; pulse slow and full; breathing heavy.

A blister to the neck; cold lotion to the head; a dose of croton oil to act on the bowels, which had been sluggish for some days.

Next day he became more sensible, but much inclined to coma, with a bloated countenance and heavy pulse. My assistant ordered four leeches to the temples, and blisters behind the ears.

20th.—Quite sensible; bowels open; has no paralysis.

22d.—Passed a restless night, and is irritable.

Purgative mixture; and a morphia draught at night.

23d.—Slept well, and is better. He continued the aperient medicines for some days, and is now quite well.

CASE IV.—J. D. æt. 60, short and rather stout, was seized with hemiplegia on the 15th of September, 1842. He was seen soon after the attack, and treated by blister to the neck and warm purgative draughts. Arteries somewhat ossified.

October 12th.—He now walks about without difficulty, complaining only of weakness in the affected limbs.

CASE V.—M. F., æt. 80 years, a spare, active old woman, was attacked on Friday, Nov. 5th, 1841, just after a hard day's work at the wash-tub, with pain in the head, quickly followed by total insensibility. Next day I was sent for, and found her in profound apoplexy. Stertorous breathing; bronchial rattle; total insensibility. She had been in this state all night. Not able to swallow; pulse feeble.

Empl. Lyttæ amplum Nuchæ. Mustard poultices to the legs.

7th.—Blister drawn. Can now be roused so as to answer questions distinctly, and can move the right leg and arm; left side appears to be paralysed. Has taken some gruel and castor oil.

8th.—Same as yesterday. Bowels not relieved.

Mist. Cathart. 4tis horis.

9th.—More drowsy to-day. Bowels not open.

10th.—Died.

CASE VI.—Ann Ellis, 75 years of age, seized with apoplexy May 17th, 1842. I found her quite insensible; breathing very much impeded with mucous rattle; surface pale, cold, and clammy; pulse almost imperceptible: she seemed to be within a few minutes of her death. I ordered a little warm brandy and water, and left the house, not expecting to see her again. She however rallied, and recovered her sensibility to some extent, until the 25th, when she again became comatose, slightly convulsed, and died.

Although these two last cases proved fatal, they are calculated to exemplify the effort which nature is able to make towards restoration, even when there is serious and fatal mischief in the brain; and surely it is wise and reasonable not to prevent it by depletory treatment, which must necessarily remove every

chance of spontaneous reanimation. Who can say that these two women might not have recovered, if their *vis vitæ* had been more vigorous? The mischief to the brain must have happened at the first; if partial recovery take place in spite of this, who can point out the degree to which it might proceed where the constitutional strength can be supported? The *vis medicatrix* is sufficient to repair external injuries of the severest character, where the constitution can be maintained in a fair degree of vigour. We see daily cases of recovery from fevers and internal inflammations, where parts of delicate construction, and important to life, have been severely, almost mortally, implicated; the remedial agent being this same *vis medicatrix*, assisted by such means as we possess for supporting the powers of the constitution. In some chronic cases of organic disease, we witness the same power at work to delay the fatal result as long as possible; the length of time being often proportionate to the degree in which art is able to support the general strength. Why are we to distrust this powerful agent where disease or injury of the brain is the cause of danger? Do not some of the cases I have related prove it to be efficient? It is said, that by letting blood freely in cases of apoplexy, extravasation may be stopped, and further mischief prevented. But what has been the result of such large depletions? Unfortunately the recoveries are far too small in number to warrant any just inference in favour of this usual plan of treatment; and when it is considered that bleeding will sometimes itself produce the symptoms under which apoplectics die, surely we should pause to inquire whether such fatal issue may not be the effect of the treatment, rather than the necessary consequence of the disease.

“Magnæ sanguinis detractiones, graves et fere perniciosiores effectus habent; arteriis enim variisque cordis saccis multum et subito relaxatis, viribusque eorum sic imminutis, sanguinis impetus ades deficit, ut ad excitandum snisque muneribus aptandum cerebrum non amplius sufficiat, unde vertigo, nausea, vomitus, animi defectio, et non modo cordis arteriarumque actio, sed omnis motus atque sensus interruptus.”

“Ingens et subita sanguinis jactura omnibus brevi et multum nocet, nec raro mortem affert. Hæc enim non modo insignem debilitatem, et vertiginem et nauseam, aut vomitum et animi defectionem, sed convulsiones quoque generales, et plerumque lethales, inducit.”—*Gregory's Conspectus.*

“Largæ et repetitæ sanguinis detractiones omnibus apoplecticis et paralyticis, nullo delectu habito, utiliter aut tuto adhiberi certe non possunt. Etenim juniores, et robusti, non tam obnoxii sunt his morbis, quam pueri infirmi, et effæti senes, in quibus vires nutriendæ sunt, et excitandæ, potius quam minuendæ; dum multa sanguinis profusio omnes naturæ conatus reprimat, et tenues vitæ reliquias penitus extinguit. Quod si consulamus experientiam, hæc, quantum possum judicare, testatur copias sanguinis missiones sæpe nocuisse, easque in non paucis ægrotis tutius fuisse prætermittas.”—*Heberden, Comment. p. 300*

In the first case, and probably in the second, emetics produced very beneficial effects; and by some few practitioners they have been considered the proper remedy for apoplexy. Yet is the fear of their being injurious so prevalent, that we are advised strictly to avoid them. Abercrombie says, “the use of emetics in apoplexy is as old as the days of Aretæus, and they have been employed at different times by physicians of the first eminence, among whom may be mentioned Etmüller, Sydenham, Boerhaave, and Lieutaud; and the practice must therefore have some foundation in observation and experience. There can be little doubt that, in the early stage of any apoplectic affection, the use of an emetic would be a very hazardous practice.” He, however, strongly recommends purgation. “This is always to be considered as a most important and leading point in the treatment of apoplexy; and though, in arresting the progress of the disease, our first reliance is upon large and repeated bleeding, the first decided improvement of the patient is generally under the influence of powerful purging.” (On Diseases of the Brain, p. 289).

Now when we bring our unbiassed judgment and experience to bear upon the question of the comparative safety of emetics and purgatives, what do we find to be the result? Why, that we can find scarcely a case where apoplexy

has been produced by the operation of an emetic, whereas it is not an unusual occurrence for a person to have a seizure during an evacuation of the bowels. I believe this is an indisputable fact, and to my mind is quite decisive of the act of vomiting being as harmless, if not more so, than that of alvine evacuation.

I think it must be allowed by every candid observer that the legitimate inference to be drawn from my own experience of apoplexy, as exhibited in the cases I have published, is, that the non-depletory mode of treatment is the most successful: the reported cases of other practitioners indirectly corroborate this inference. I have collected them in large numbers; the treatment has been, for the most part, profuse expenditure of blood; and the deaths awfully numerous.

It would be absurd to doubt that the cultivation of morbid anatomy has been immensely beneficial to the practice of medicine; but it appears that, with reference to diseases of the brain, it has overstepped its proper bounds, and usurped the position which the practical experience of the past and present ages is entitled to maintain. Nearly all our reasoning with respect to the treatment of apoplexy is founded upon certain post-mortem appearances, some of which are probably more the consequence of death than of disease; the treatment itself is not based upon what has been successful in curing the disease (for the usual plan is eminently unsuccessful), but upon arguments, brought forward with no slight degree of plausibility, concerning the occurrence, causes, and removal, of extravasation of blood or serum in the brain. It is well known that such extravasation is not the only cause of even fatal apoplexy, for cases have occurred where no diseased appearances have been discovered in the brain after death. It has been shown, by others as well as myself, that apoplexy, severe and threatening, has been cured without bleeding: the opinion that it can be so cured appears to be slowly gaining ground. Let us put aside for a while our preconceived notions, and by patient examination of the effects of remedies, endeavour to enhance the credit of our art by lessening the fatality of this serious disease. Perhaps it must still be granted that venesection is advisable in some cases of apoplexy: I believe

these cases to be very rare; for I have seen the heat of skin, flushed countenance, strong and rapid pulse, laborious breathing, convulsions,—symptoms indicative, if any, of the necessity of abstracting blood—give way under the simple employment of cold to the shorn scalp, and purgative clysters, without the assistance of any depletory measures likely to occasion subsequent loss of power. What could apparently be more desperate than the situation of my patient (Case II.) at noon on the 28th of June? The satisfactory removal of the severe symptoms, and the present convalescent state of the patient, are the best arguments in favour of caution and moderation; and the best answer to the theory that, in apoplexy, the only way to preserve life is, by art, almost to destroy it.

“Serum est cavendi tempus in mediis malis.”

I had just completed this paper, when, on the morning of the 13th of October, I was summoned to attend Mrs. A., whose case I have already related (No. II.) She had been subjected to more excitement than usual, made two or three calls the day before, and afterwards dined off food not easy of digestion. About 5 o'clock A.M. she awoke her husband by grasping his hand, but could not speak. She rallied a little, and was assisted out of bed to the night-chair. The bowels were relieved; and as she became drowsy and slightly convulsed, I was sent for. She was comatose, with rather full pulse and perspiration. Drew up her legs when I tickled her feet. Could not rouse her; but during my attempts to make her speak her face became horribly distorted, and she had a severe general convulsion of some minutes' duration; she remained quite comatose after the convulsion had subsided. I applied cold cloths to the scalp, and gave a strong purgative injection. In three hours I visited her again: the coma had remained about an hour after I had left, and the bowels had acted freely; she had vomited a little bilious matter; there had been no more convulsion. She could now articulate tolerably well, and was sensible enough to ask me to dress her issue; she had chilled once or twice, and removed the cold application from her head; and when her arm was uncovered during the dressing it became cold, and all

"goose-flesh." Would it have been safe to have reduced the heat of skin and strength of pulse by withdrawing blood at first? In the evening another injection was given: she was more sensible; but the tongue was foul, and she complained much of pain in the head.

Cold vinegar and water to the forehead.

15th.—Another injection, followed by relief from the bowels, and perfect restoration of her senses; pulse quiet; tongue much cleaner. Ate some breakfast, and was well enough to settle wages with a servant who was about to leave.

Cottishall, West Norwich,
October 16th, 1842.

MR. LISTON'S "VARIETY OF FALSE ANEURISM."

To the Editor of the Medical Gazette.

SIR,

UNDER the conviction that by withholding from the public the whole truth of the following much controverted case, I should incur the imputation of moral cowardice, I venture to claim a small space in your just and temperate pages. A false precedent with a great name attached to it is as likely to be pernicious in medical as in legal science: and he who conceals the truth from motives of interest or fear, is only less guilty than he who assiduously promulgates falsehood to screen himself from merited blame.

As House-Surgeon to University College Hospital, under Mr. Liston, on the 20th Oct. 1841, I examined a boy who had presented himself a few minutes before that gentleman's visit. His mother attended with him, and gave, partly at that time, partly afterwards, the following short history of the case, which I copy verbatim from the Hospital Case-Book, as it was drawn up by the dresser for the week, Mr. Colechester.

"George Anthony, æt. 12, admitted Oct. 20th: has been a healthy child until, six years ago, he had measles and whooping-cough, which left him in a very reduced state. About two months ago he had a violent cough and much fever: at this time a small swelling was first observed just below the ear; it was soft, and might be easily and entirely dispersed by pressure. This

was shown to the surgeon of the parish, who attended him, but as he gave no directions with regard to it, his mother applied fomentations and poultices. It has increased gradually and slowly until the last three or four days, when its progress was more rapid and irregular," &c. I examined it in the presence of some students, and expressed my belief that it was an aneurism. When Mr. Liston came at 2 p.m., as the case was important I told him immediately "that there was a boy among the out-patients with a swelling in his neck which seemed to me like an aneurism." Mr. Liston quickly came to the patient, and observed, "You don't get aneurism in boys like that." It was my duty to carry instruments. Mr. Liston asked for "something to make a puncture with." I offered an exploring needle; he said, "he did not want a thing like that." I then offered a small tendon needle; he seemed angry, and produced from his own pocket several bistouries, from which he selected a full-sized one, and made with it an incision into the swelling, in a perpendicular direction. Arterial blood spirted out by the sides of the bistoury. Mr. Liston observed, it was "an anomalous tumor," and changing the position of his knife, held it horizontally, so that the sides of the incision were kept separate; the blood now came out in a thick gush; fainting quickly ensued, and the boy remained in an almost pulseless state for three hours. Mr. Liston closed the incision by means of three hare-lip pins and the twisted suture. There was not the slightest appearance of pus in the blood. The incision was not a small one, or made with a narrow bistoury; otherwise, why should three hare-lip pins and the twisted suture be necessary to close it? After the lamentable nature of the mistake became apparent, a student asked if a bruit had not been heard. I answered, "yes;" and Mr. Liston, after I had done all in my power to prevent the misfortune, attempted to attach blame to me for not having mentioned this symptom before. The reasons why I did not do so were, 1stly, Because, as a diagnostic symptom of aneurism, I believed it to be worthless: any unequal pressure exerted upon a healthy artery, as by a tumor, or by the stethoscope itself, will produce a bruit. And, 2dly, Because Mr. Liston permitted me

to say but little on the subject. At my request alone, he went to the window to examine the swelling between the fauces, where I told him I doubted if a thrill were not perceptible. He turned away abruptly, and insisted on making the incision in the manner above stated. Surely, in my anxiety to prevent a mistake, I overstepped the bounds of my duty in saying what I did. It could not be my duty to instruct Mr. Liston in the nature of his cases. But to return. The incision was made at 2 P.M.; reaction did not occur until 5 P.M.; and from that time until 4 the next morning, the swelling increased very much, becoming hard, tense, and bluish, and extending downwards to the clavicle, and inwards to such a degree as to produce great danger of suffocation by pressure on the trachea and larynx: the diffusion of the aneurism also threw great stress upon the pins. I sat up with the patient all night, little expecting he would survive until morning; the danger of suffocation, or of hæmorrhage from the giving way of the sutures, seemed so imminent. From 4 A.M. until 2 P.M. on the 21st, when the carotid was tied, the symptoms were less urgent. To quote from Mr. Liston's account of the operation, given in his pamphlet, "The great difficulty arose from the necessary smallness of the incision; the tumor extended downwards so low in the neck that it was impossible to extend the incision upwards, and the artery, which appeared to be at a very great depth from the surface, was to be sought for at the bottom of a small hole." The poor patient died of hæmorrhage from the wound of the operation at 5 P.M., Nov. 5th. At the *post-mortem*, "the ligature was found to have been placed close to the origin of the carotid from the innominata;" "the proximal end of the vessel was quite open;" "there had been no attempt at the formation of a clot."

Much of the above detail may be thought tedious, but where different statements have been made, it is necessary to be explicit. Mr. Liston has lately published this case, in a pamphlet, entitled "On a variety of false Aneurism," in which he attempts to prove that it was originally an abscess, and adduces several other cases in support of this explanation: but it is remarkable that none of the latter are in

any degree similar to it. Two of them, namely the third and the last, are plainly referrible to diffuse inflammation of the cellular tissue, producing lesion of the arterial tunics; and the others to ulceration into an artery from the cyst of an abscess after the evacuation of the latter. Where is the proof that the aneurism in G. Anthony's case was ever an abscess? The swelling at first disappeared under pressure. Mr. Liston supposes that the pus which once filled the cavity was washed into the circulation by the current of blood. Now although pus is frequently without danger taken up by the absorbents, in which operation it probably undergoes a great change, when was so much as half an ounce or an ounce of that fluid ever known to be admitted immediately and at once into the circulation without fearful constitutional irritation, purulent deposits, and generally death? Yet no constitutional symptoms followed the appearance of the swelling in this case. Whether it was a true or false aneurism, according to Hodgson, or Scarpa, or others, *it was a cavity communicating with an artery and containing arterial blood*. Before it was opened it did not externally seem so large as a hen's egg, and was situated quite high up in the neck, as is proved by its progressing so much between the fauces: and if the carotid had been tied immediately after the unfortunate incision, the boy's life might have been saved. There is plenty of daylight after two o'clock at this time of the year; and if it were otherwise an operation so urgently demanded ought to have been performed by artificial light. The circumscribed was converted into the diffused aneurism at 2 P.M., but not until 5 P.M. did reaction occur, and the swelling increase, by blood being injected into the cellular tissue around; and after a delay of twenty-four hours the increase was so great, that no chance of success was afforded to the operation. I know a case in which a popliteal aneurism was punctured by mistake, but the eminent surgeon who made it tied the femoral artery without delay, and thus did his best to remedy the blunder, without attempting to prove that the aneurism was a false one.

It is very unfortunate that Mr. Liston did not inform himself more correctly of the age of the patient, as he thinks the question of age so important,

in determining the nature of the swelling. The mother of the boy on two occasions stated to me that his age was *twelve years*; and I wrote that age on the card at the head of his bed. The card remains to prove it. The mother must have made the same statement to Mr. Colchester, as the hospital case-book testifies, and every student in attendance must have known the same fact.

I have been more nearly concerned in this unfortunate case than any other person, except Mr. Liston, no hostile feeling towards whom, has prompted this publication of the simple truth. If any other public officer had pursued the same line of conduct, I should have thought the same plain duty alone remained to

Your obedient servant,

JOHN CHARLES BUCKNILL, M.B.
M.R.C.S., Late House Surgeon to the University College Hospital, late President to the University College Medical Society.

8, Westbourne Place,
Eaton Square.

ON

DUTCH MEDICAL INSTITUTIONS.

By EDWIN LEE.

(For the *London Medical Gazette*.)

[Continued from p. 111.]

THERE are also, at Amsterdam, an hospital for the Jews, and one, half a mile from the town, for chronic cases, syphilitic and insane patients. The latter contains about 450 beds. There are no visiting physicians, all the inmates being under the superintendence of a resident medical attendant; and, as far as the insane patients are concerned, the place may be considered merely as a house of detention, as no treatment appears to be adopted. The number is about 150, the greater part females. The wards are small, dirty, and close, containing about 20 beds each, the beds almost touching each other; this is likewise the case in the wards for the more furious patients, which presents altogether a distressing and disgraceful spectacle. A new building, however, is now in progress on the road to Haarlem, for the reception of the insane, who will there be subjected to more regular and methodical treatment. The syphilitic pa-

tients are, for the most part, lodged in a small detached building; almost all of them are labouring under secondary symptoms, which circumstance is ascribed to the neglect of applying for relief when merely affected with primary symptoms, notwithstanding prostitutes are said to be subject to the control of the police; and even if a female affected with syphilis desires to leave the hospital before she is cured, the physician has no power to prevent her. The treatment consists principally in the internal exhibition of mercury; the oxymuriate is generally preferred. In some cases, iodine is combined with mercurial preparations.

Utrecht is a handsome town, containing about 40,000 inhabitants. The university is inferior to that of Leyden, the number of students not being more than two-thirds. There are two or three museums (Blenland's and Lidth's) of comparative anatomy and zoology, which, however, present nothing very attractive to those who have seen others of more importance. Professor Schroeder Vanderkolk occupies the chair of anatomy and physiology; Loucq, that of special pathology and therapeutics; Suerman, surgery; B. F. Suerman, general pathology, therapeutics, and materia medica; Mulder, surgical operations and obstetricity; Alexander, ophthalmology. The hospital (*Ziekenhuis*) is situate near the end of the town, and surrounded with narrow streets. It contains about 100 beds, from eight to sixteen in each ward. In the upper story of the central portion are the female patients, the men occupying the larger wing, while the smaller wing is appropriated to the cliniques. The hospital for the insane is a large building, in a more open situation, at the opposite end of the town. Curable and incurable patients are admitted. They are divided into three classes, according to the amount of their payments: the lowest class pay 150, the next 300, and the highest 800 florins per annum. The two higher classes are lodged in rooms containing from one to three beds; the other class sleep in wards of about sixteen beds, lofty, clean, and well ventilated. The furious patients are placed in isolated dark cells till they become more tranquil: the only means of personal restraint which is adopted is the strait waistcoat. The douche is a good deal em-

ployed in the treatment. Many of the patients are employed in various kinds of occupation, though but little in the open air.

170, North Street, Brighton,
Oct. 20, 1842.

CASE OF
CENTRAL LACERATION OF THE
PERINEUM DURING LABOUR.

To the Editor of the Medical Gazette.

SIR

IF you consider the following case of sufficient interest to the medical profession, perhaps you will do me the favour of inserting it in the pages of your valuable journal, and oblige yours,

Very obediently,

T. C. COWARD, M.R.C.S.

5, High-street, Stepney, Oct. 24, 1842.

Mrs. B., of Stepney, æt. 21, of rather a strumous diathesis, engaged me to attend her in her confinement. I was called at 10 A.M. 7th of April last, and was informed she had been in slight pain for several hours; found the os uteri thoroughly dilated, and the head of the fœtus descending, the pains very forcible, and every thing had the appearance of a happy termination. I was a little surprised, however, after a short period, to find that the head pressed strongly against the back part of the perineum and anus, distending those parts enormously without effecting any dilatation of the external parts, notwithstanding all the support I could give to incline the head to the arch of the pubis. At length, during a severe pain, she complained of something cracking; indeed I felt it myself give way under my hand; and on examination found a laceration about an inch and half long, extending across the perineum close to the sphincter ani, from which arterial blood was escaping in a small stream. I then began to fear that notwithstanding all I could do to prevent, the child would escape there. I immediately called in a brother practitioner, and by our joint efforts we succeeded in delivering the head through the natural outlet in about half an hour; but the same pain which brought the head forced the shoulder and elbow through the perineum, causing a dreadful laceration. The placenta soon followed, and the

uterus contracted well. We then made an examination, my friend introducing his finger by the vagina, while I did the same by the anus, and found the recto-vaginal septum torn to the extent of two inches, a few fibres of the sphincter, and the whole of the perineum, with the exception of about half an inch of fourchette. We merely sponged the parts and tied the legs together, and about three hours afterwards Dr. F. H. Ramsbotham saw the case with us, and directed two sutures to be applied; the bowels to be kept confined for a week, and the catheter to be used twice a day. All this was done; the parts however sloughed, and the ligatures with a considerable portion of the neighbouring structures came away. Poultices were used; and on giving an aperient at the end of a week, had the satisfaction of finding that the evacuations came through the natural passage. The black and zinc lotions were used, and by supporting her strength with wine, tonics &c., in three months the parts had granulated, but the vagina was much contracted. She left town for the country.

In making a few remarks on this case, it is very important to know the cause of such an accident, with a view to its future prevention. Here due support was unremittingly given by me to the perineum. I certainly remarked that the sacrum seemed straighter than usual; that from the sphincter to the fourchette there was an unusual length, and its fibre seemed softer than natural. I could not account, however, for the obstinate rigidity of the external parts until the other day I was reading Dr. Ingleby's excellent practical work on Obstetric Medicine, wherein he accounts for it by the parties, when children, having chronic inflammation with discharge, so customary in the strumous habit. I therefore made inquiries of the mother of my patient, and found that for two or three years, when a girl, she had a troublesome discharge, and was obliged to use lotions with syringe &c., which, I have no doubt, gave rise to the preternatural thickening and rigidity of the external parts.

I have been led to make these remarks from an idea that a case like the one I have just related might happen to a young practitioner just commencing his career, and the world might condemn him for ignorance or inattention,

when I am convinced, even by the best directed efforts, such an accident can rarely be prevented; at all events, I know of no means unless, it would be justifiable to anticipate the laceration by the use of the scalpel.

ON THE DIVISION OF MEDICAL LABOUR.

By ROBERT HULL, M.D.

(For the *London Medical Gazette*.)

The Hospital Physician.

It may appear superfluous to define the character of this practitioner. It *was* unnecessary twenty years ago: it is imperative *now*. The licentiousness of reform, which has distressed, nearly subverted, the empire, has ramified into our once concordant art; and, unless the eyes of its professors are opened, will vitally damage its benefits. I say benefits, for, after all, the public are chiefly to be respected, when we discuss the novel amalgamation of departments; and I declare, with a venerated physician of the west, "to me personally this will be of no consequence; to the lives of the public, a confusion of pursuits may hereafter be of great."

It is now necessary to ask the question, "Who is to be the physician in a hospital?" It is plainly answered by the rules of every institution. If not plainly, the answer is *assumed*; an indirect evidence, stronger than the written regulation. The bare term implies that he is to be a physician; not a surgeon. He is to be not merely restricted to medicine in the hospital; but he is not to be elected to the charity unless, out of it, he practises as a pure physician.

The divisions of our art do not regard the studies, but the *practice*. All of us are supposed to enjoy a primordial and common substratum of tuition. All are supposed subsequently to select their peculiar walk.

The general practiser who becomes a physician, no matter at what period of his life, only extends his primordial education, enriched by experience; the longer, perhaps, the better. *When* he is promoted, he is expected to confine his studies, observations, *trade*, to simple physic. The division equally de-

manded by science, by the wants of the public, by the fraternity of medical men, is of *labour*, not of learning.

This has been provided by the founders of hospitals: otherwise the distinction of titles is absurd; otherwise the six, or twelve officers, should be designated by a common name, and execute common duties. This is so obvious, that even the irregulars deny it not. They take precious care to be circumspect within the walls. They never brandish the scalpel, nor raise the pullies, nor adjust the bandage. They procure the surgeon's hand to open their dead patients.

No. They are amenable to the governors; and they dread an expulsion. But, secure from official stigmata, they violate "division" in private practice. They operate abroad. Is this logical? Is this manly? I simply put the question—is this exactly honourable? They concede the principle of divided labour where they *must* concede; they evade it where no laws can enforce.

The medical body, the public, should remember that this maintenance of discipline within a hospital does not prevent the mischiefs which *all* suffer from out-door abnormities. The irregulars themselves testify to the advantages of divided labour: otherwise, why do they submit to limitation inside their respective institutions. Their own manhood, virtue, consistency, should induce them to spurn a separation of departments in *official* routine, which they disclaim in their private proceedings. Will they allow that interest, low, selfish considerations compel them to wink at an arrangement which, in their hearts, they believe to be unjust—not founded on the public wants—hostile to science?

Behold the dilemma! If they believe promiscuous practice the proper, why do they violate their sentiments by submitting to the discipline of office? If they believe it, as their hospital passivity implies, wrong and pernicious, why do they get a private living by condemnable methods?

But "what harm can they inflict on their hospital patients by their private promiscuities?" What harm? all that can be effected by the violation of divided labour; by their non-concentration of study, skill, power, on simple medicine. Yet this concentration the

governors of hospitals expect. They entrust the pitiable poor to the surgery of the surgeon. They demand for the non-surgical patients the medical attendance of the pure physician. For my part, I do not understand how a conscientious gentleman can undertake the office of hospital physician, unless he conform to the intentions of the subscribers.

To those hospitals—at present, most happily, few—where an operator officiates as a physician, it may be said the governors elected him with open eyes. Of this I am not so certain. In one institution, where the office was contested by two gentlemen, one a pure physician, the other amphibious, it is true that the real physician, accomplished and unexceptionable, was vanquished; yet not at the poll; he retired through prescience of defeat. But it was expected by subscribers, who otherwise would actively have opposed him, that the successful aspirant would relinquish his surgery when installed in his office.

But even were the statement well founded, that subscribers would advisedly elect an operator as a physician, then I should say, the laity cannot judge in this therapeutic business; and instead of a republican charity, managed by the popular opinion, give *me* the monarchic or aristocratic selection; give me such an establishment as that of Guy.

In this magnificent hospital we shall never hear that the office of physician is filled by any practiser, whose body and soul are dedicated to absorbing surgery.

But I will not believe that there exists in England a hospital, whose supporters would, if they understood their man, elect a hybrid to the office of unmixed physician. Fancy such a circular as the following; prophesy the result.

MY LORD,—I solicit your vote for the office of Physician to the Epsom Hospital, rendered vacant by the death of Dr. Racer. I can boast superior claims. I am an operating surgeon, and *therefore* peculiarly fitted for a medical position. I am devoted to the knife; and, *therefore*, earnestly covet a post instituted for the practitioner, who never handles it. I love the chirurgery of the healing art, to which I dedicate my time and studies—my soul and

strength; and, *therefore*, I supplicate your interest for an office which demands all my powers to be exerted in an opposite direction. Should I reach this summit of my ambition, I promise your Lordship to consecrate to the medical cases all those energies which my preference of operations may leave to me; all that time which an extensive trade in surgery enables me to spare.

Your Lordship's, until death,

NICHOLAS OMNIBUS, M.D."

The division of labour is too sparing, not too multiplicitous. This is shown in the metropolis, where full and successful play is given to the divisional arrangements. See the varieties of excellence in the same body of physicians: one intelligent of cerebral disorders; another heartily devoted to cardiac; a third inspired with pulmonic pursuits; a fourth near dying from investigations of the liver: all, authorities in their peculiar departments! So in the surgical arena: the herniotomist; the lithotomist: the amputator; the pathologist; *good* for joint-evil!

Promiscuous labour cannot, logically nor consistently, step within the boundaries of a particular craft nor profession. If a man deserve those sneers which have been expressed towards him from a London chair, because he does not impudently pretend to universality in medicine, he is likewise contemptible because he does not expatiate, genius-like, beyond it. Crichtonian perfection implies a circle of sciences. *The Duke* should unite, in his own person, the delivery of the nation and that of the Queen; and Dr. Locoek is no philosopher, unless he can extricate an army from peril as well as a royal infant from straits.

But who is to be the hospital physician? If the surgeon, why not the apothecary? If the possession of a doctorate justifies the first, the second must not be excluded.

Then we shall see *Dr. Variorum*, the surgeon, apothecary, and man-midwife, perhaps the keeper of an *open* shop, a candidate for the office of physician to a west-end hospital; and the proud physician of St. George's may be called on to meet in consultation a colleague, who will "make up" the prescription which results; *unless*, before this threatened era, every gentleman shall have left the profession; and the pub-

lie, *who will richly deserve it*, be kept in repair by druggists, hucksters, sansculottes.

The precedence, which hitherto has been conceded cheerfully to the physician, is founded on his isolation, purity, non-rivalry. Private life, the public hospital, have religiously maintained his privileges and honour. But can we expect that surgeon J., or K., or L., shall manifest courtesy or deference to *Dr. Omnibus*, who invades his department? Is Mr. J. to find a rival operator, about the town, in *Dr. Omnibus*; and yet pay him the courtesy of a hospital colleague in medicine, when, perhaps, Mr. J. is vastly superior even in that compartment of healing? Is J., the surgeon, eminent as he is for courtesy, for gentlemanly bearing, for deference to the abstract medicus, for conservation of professional ranks; is he to push this sentiment to the extreme: equally respectful to the regular and the disruptor; to the man who consults the surgeon's pocket, and to him who pockets the surgeon's fee? Is Mr. J. to be "called in over him" in private life, but to give him the pass in the public hospital? See what commotions, quarrels, feuds, arise out of these irregular movements! I knew a provincial town, once famed for its professional army, torn to rags of discontent and bickering, through this sad departure from discipline. How should it be otherwise? First, the innovator himself, his surgical hand against every body! Then his backers—the few silly, or servile, or selfish men, whom he can get to back him, distasteful to the friends of order. Then the loyal themselves, *sick* of endless animosities, giving up the contest in lamentable trepidation. Then the per-paucissimi, who still remain impavid among the ruins of their corps, alone, unsupported, disliked for their tenacity. Contempt, or hate, or alienation, every where. Friendships broken; consultations evaded; the public chuckling over the *Bellum Intestinum*! Sure, after all, to patronize the irregular; and deserving to suffer all the present, all the future, consequences of their ignoble interference.

I long for "the restoration." The rebellious have perpetrated so much mischief, that I should hail the return to order, even though effected by a despotic pacificant. I tremble at legis-

lative interference in a cause which ought not to require it. I should like to see the parliament impenetrably deaf to reforming clamour; deserving the eulogy which was addressed by Pliny to an ancient quieter of factions—"Pacem reddidisti; excidisti intestinum malum, et provida severitate cavisti, ne fundata legibus civitas, eversa legibus videretur."

I wish the parliament would say, "Settle it, gentlemen, among yourselves: you have plenty of corporations, and a sufficient number of parliamentary acts to uphold them. Do you *your* duty; scout the irregulars; consociate only with the fair practitioner; cultivate the fastidious, the honourable, the just: then may you fear no evil from druggists nor charlatans. If an occasional attempt be made to injure your interests, and violate your established habits, show that you have "pluck" as well as perception; and imitate the admirable example set you by Messrs. Bateson and Howitt, of Lancaster. You will thus effect more benefit to your corps than by rambling over the country in unprecedented associations, with croaking twaddle about reform, and candied compliments to each other.

Cease to make stare the rural population, north, south, east, or west."

Ξυνήλθομεν δὲ βουχόλοι καὶ ποιμένες,
χαίνων λόγων δώσαντες, ἀλλήλοις ἔριν,
ἕως δεινὰ δρῶσι θαυμάτων τ' ἐπάγια.

MEDICAL GAZETTE.

Friday, October 28, 1842.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

HEALTH OF THE POOR.

SOME years since we quoted the case of an eminent philosopher, who was afflicted with a partial amaurosis. His eyes refused one half of their duty, so that if he attempted, for example, to read a name on a door, he saw the first letters only, while the latter ones were shrouded in darkness.

In like manner, the Poor Law Com-

missioners, when they attempt to ascertain why disease sweeps away the indigent with double virulence, can see but one half of the causes; dirt and want of ventilation they can spy at the distance of 500 miles; but put down STARVATION in the largest letters, and their optic nerves are no longer susceptible of impression.

The censorious, indeed, might quote the adage "None are so blind as those that will not see"; and might observe that evidence is to be found in the appendices on the subject of starvation, of which no abstract is given in the long report before us.* In a word, the Poor Law party is not pleased with all the information it gets:

Infelix perit lucem, refugitque repertam!

Bearing in mind, therefore, this important mutilation, recollecting that we are reading the tragedy of Hamlet, with the part of Hamlet omitted by particular desire, we will touch upon some of the principal points in this elaborate report.

The first point which he touched upon is the mortality resulting from preventible causes. It seems that the deaths in England and Wales from epidemic, endemic, and contagious diseases, including the heads of fever, typhus, and scarlatina, amounted, in 1838, to 56,461; "the great proportion of which," says, the author "are proved to be preventible."

He also justly refers a portion of the mortality under other heads, as, for instance, diseases of the respiratory or digestive organs, to the bad condition of the dwellings of the poor. Thus Mr. Gilbert, the Assistant Commissioner, when acting in Cornwall and Devon, found that there was a large district in Tiverton, where fever was pre-

valent. The land is nearly on a level with the water, the ground marshy, and the sewers open. The local authorities have in vain endeavoured to compel the occupants of the houses to remove nuisances and cover the drains; like the cottagers of Glenburnie, the men of Tiverton "winna be fashed," and their reform can only proceed from the friendly severity of the legislature.

Similar evils, in all their painful varieties, prevail throughout Great Britain. According to Mr. Parker, Windsor is beyond comparison the worst of all the towns he has visited. "From the gas-works at the end of George street a double line of open, deep, black, and stagnant ditches extends to Clewer-lane. From these ditches an intolerable stench is perpetually rising, and produces fever of a severe character."

Evidence of the same species comes from the medical officers of the Epping, West Ham, Bromley, Wolverhampton, Macclesfield, Stockport, Wigan, Teesdale, and other unions.

Sometimes, the cottages are neither wind nor water-tight, and the medical officer attends labours, where the wet runs down the walls, and the light can be seen through the roof. Sometimes the cottagers live near ditches, into which privies and pig-sties empty themselves.* In this place, there is a court crowded with Irish, and near it a constant pool of green water or mud; in that one, there appears to be a drain which has been choked up, the stench from which is intolerable.

The town of Stafford has become used

* Report to her Majesty's principal Secretary of State for the Home Department, from the Poor Law Commissioners, on an inquiry into the sanitary condition of the labouring population of Great Britain; with appendices. Presented to both Houses of Parliament, by command of her Majesty, July 1842. London, 1842.

* Another thing that contributes not a little to the diseases of boors, is their slothful carelessness in heaping up the dung designed for improving their grounds, just before their cow-houses and hog-sties, and at the very doors of their dwelling-houses, and keeping it there for a nosegay all summer; for at this rate the air they live in must needs be polluted with the foul steams that rise incessantly."—(Ramazzini's Treatise on the Diseases of Tradesmen, English edition of 1705.)

to its dirt: "a local act for the improvement of the town," says Dr. Edward Knight, "empowers the commissioners to remove nuisances; but no notice is ever taken."

In Liverpool, a medical officer attended a family of 13, twelve of whom had typhus fever, without a bed in the *cellar*, without straw or timber shavings frequent substitutes. They lay on the floor, and so crowded, that I could scarcely pass between them." In another house he attended fourteen patients, with only two beds in the house.

The Rev. Dr. Gilly, Canon of Durham, has lately made an appeal in behalf of the border peasantry, whose cottages are patterns of wretchedness. The floor is of earth, the windows do not open, and there is neither pump nor well. The rafters are rotten and displaced, and the thatch, says the reverend philanthropist, looks more like the top of a dunghill than of a cottage.

To judge from the group of Northumbrian cottages copied from Dr. Gilly, and given in this Report, they resemble Irish huts, the *ultima Thule* of discomfort.

Still, there is a lower deep than this, and the condition of the poor in Scotland is worse. The labourers of Lochmaben inhabit buildings 30 feet in length by 16 in breadth, with a clay floor. Such a receptacle is usually occupied by two families; the partitions being formed by the backs of the beds, "which will be best understood by describing them as wooden boxes open on one side." The windows rarely open, the chimneys are bad, and as the scarcity of fuel compels the inmates to close the door, for the sake of warmth, the chamber is often full of smoke.

To see something worse still, we must follow Mr. Chadwick in company

with Dr. Arnott and others, into the wynds of Edinburgh and Glasgow. Dr. Arnott, after describing his passage through a house into a court with a dung receptacle of the most disgusting kind, and then through a second passage into a second court with a similar abomination, and then through another passage to a third court and a third dung-heap, proceeds to say:—

"There were no privies or drains there, and the dung-heaps received all filth which the swarm of wretched inhabitants could give; and we learned that a considerable part of the rent of the houses was paid by the produce of the dung-heaps. Thus, worse off than wild animals, many of which withdraw to a distance, and conceal their ordure, the dwellers in these courts had converted their shame into a kind of money by which their lodging was to be paid. The interiors of these houses and their inmates corresponded with the exterior. We saw half-dressed wretches crowding together to be warm; and in one bed, although in the middle of the day, several women were imprisoned under a blanket, because as many others who had on their backs all the articles of dress that belonged to the party, were then out of doors in the streets."

Mr. Chadwick says, that on the whole the condition of the population in Glasgow was worse than they had seen in any part of Great Britain.

According to the Poor-Law people, the moral to be deduced from these painful facts is, "teach the poor to be cleaner, and, if necessary, compel them to be so by legislative enactment." With this half moral, as far as it goes, we coincide entirely; and we should gladly hail a statute forbidding landlords to build pest-houses for their indigent fellow-subjects. But the remainder of the moral, equally true, and far more genial, and more instructive, is not to be forgotten. It is the lesson derived from these hideous scenes of misery in Scotland by Dr. Alison;

namely, that the absence of a poor-law neither teaches the indigent to rely on their own resources, nor stimulates the charity of the rich in their behalf.

The next topic discussed is the public arrangements external to the dwellings of the poor, by which their health is affected. This has already been touched upon in the preceding section, but we will not find fault with the repetition :

"decies repetita docet."

Drainage, which is often spoken of as if it had reached perfection, or nearly so, is generally defective. It is bad in Derby, Stockport, Bungay, Leeds, Liverpool, Brighton, Birmingham, Edinburgh, Trarant, Ayr, Stirling, Clitheroe, and even in London itself.

As for Liverpool, it contains 8,000 inhabited cellars, with at least 35,000 occupants! Again, the cleansing of streets and roads is most wretchedly performed. The streets inhabited by the working classes in Leeds, Liverpool, and Manchester, are in a state which beggars description. In the district called *Little Ireland*, in Manchester, the privies, besides being in a most disgraceful state, are in the proportion of 2 to 250 persons. To show the style of living in such retreats, we may mention that a cellar, once filled up as uninhabitable, is now occupied by a weaver, who stops up the drain with clay to prevent the water flowing in, yet is obliged to mop it up every morning.

At Inverness there are very few houses which can boast either water-closet or privy; and contagious fever is seldom or ever absent.

Mr. Baker applies to Leeds the observations made by Sir John Pringle on the causes of dysentery in camps, *e. g.* :—"The chief cause of dysentery appears to be the foul straw and the privies; for as soon as we had left that

ground on which we had been long encamped, the sickness visibly abated."

In St. Giles's parish, in London, Mr. Howell, a surveyor of note, has found the yard of a house covered with night-soil, to the depth of nearly six inches, from the overflowing of the privy. In Westminster, he is acquainted with numberless houses where there is no drainage, and where the cellars, being constantly flooded, the occupiers are obliged to pump out the water. This, however, is unlawful; and they have to choose between the nuisance of the stagnant water, and the paying a fine of £5. if detected.

Singularly enough, it appears that night-soil, in London, does not pay for half the expense of removal by cartage. In Edinburgh, a large proportion of the contents of the sinks, drains, and privies, is employed in irrigating the neighbouring meadows. It has decupled the value of the land, but is obviously injurious in the neighbourhood of a large town. The parties interested claim a vested right in the nuisance, and offer to discontinue the practice for a compensation of £150,000!

In London the sewerage is remarkably defective. One medical witness stated before a Committee of the House of Commons, in 1834, that four-fifths of the cases of severe typhus which he had seen were either in houses where the drains from the sewers were untrapped; or where, if trapped, they were situated opposite gully-holes; and he cited houses, where servants sleeping in the lower rooms were invariably attacked with fever.

It is impossible to conclude the present article without hopefully anticipating that the time is at hand when the legislature will put additional checks on avarice and ignorance, whether private or parochial. We trust that steps may be taken to diffuse the

enjoyment of air, light, water, and the means of rapid locomotion, at the smallest possible expense; while the law shall constantly inculcate that lesson of antique morality—

“*Sic tuo utere, ut alienum non lœdas.*”

CONVERSAZIONE AT ST. THOMAS'S.

ON Friday, the 21st inst. the first conversazione for the session, by permission of the Treasurer, Abel Chapman, Esq. was given by the teachers and lecturers of St. Thomas's Hospital. The business of the evening was opened by Mr. Grainger, by an address, in which a summary was given of the recent discoveries made by the microscope*; after which the powerful and improved oxy-hydrogen microscope, constructed by Ross, under the directions of Dr. Leeson, of St. Thomas's, was exhibited in the Theatre of the Hospital. The phenomena of polarisation were most successfully shewn, and in addition many objects which excited considerable curiosity: we were particularly struck, on first entering the great hall, with the brilliancy and effect given to the room, by the numerous lamps and magnificent microscopes which crowded the long table in the centre of the room. It was a pleasing dedication to microscopic science. In the committee room adjoining the hall, tea and coffee were liberally provided. Among the company present, which consisted of nearly six hundred persons, comprising many German, Italian, and French, in addition to many distinguished English professors, we observed R. II. Pigeon, Esq. Treasurer of Christ's Hospital; James Bentley, Esq. Treasurer of St. Bartholomew's; Prince of the Druses, Beyrout; Le Capitane Nagy de Golantha; Professor Mitscherlich, Berlin; Professor Cupari; Dr. Dieffenbach; M. de la Stoll; Sir G. Lefevre; W. Williams, Esq. M.P.; Professor Brande; Professor Cooper, and many other distinguished men.

THE HOSPITALS OF ITALY.

BY DR STRICKER.

[Concluded from p. 123.]

Catania.—This town contains two very interesting cabinets, the one belonging to Maravigna, the Professor, and the Biscari Museum. The former contains a geognostic collection from the whole of Italy, complete specimens of the forms of lava from Etna

and Vesuvius, the shells of Sicily, numerous fossils, and lastly, some very beautiful pieces of amber shot with blue, as it is found on this coast. The collection of natural history, which is ill arranged, forms only a part of the Biscari Museum. It contains lava, Sicilian marbles, shells, minerals, monsters, &c.

Messina.—On account of its loyal behaviour in the Sicilian revolution of 1837, Messina was presented with a small university. It contains a handsome anatomical theatre, an unimportant botanical garden, and a library of 18,000 volumes. The *Ospedale Civile* is situated in the suburb. At the time of my visit, typhus fever prevailed there, which was successfully treated with tartar emetic, local and general blood-letting, washing with vinegar, and tepid baths. Besides the wards for patients, it contains the foundling hospital, in which from 35 to 50 children are received monthly. Many of them are sent to board in the country, for which the payment is a piastre a month.

The boys are kept till their seventh year, the girls till their fifth, and then, if they are not adopted, are transferred to the *Conservatorio*, or orphan asylum. In the lying-in hospital, which contains twelve beds, pregnant women are received during the eighth month.

Rome.—The chief hospital at Rome, for men alone, is the *San Spirito*, near Mount St. Angelo, on both sides of the street. This hospital is capable of containing 2000 patients, and comprehends the lunatic asylum, and the penitentiary for women, *San Michele*. The lunatic asylum, which is still fitted up in the old way, with chains, &c., is not shown to strangers. The medical *clinique* in the hospital is conducted by De Matteis: it consists merely of lectures in a separate theatre. The wards are very large, the kitchen and apothecary's shop well arranged; the latter is provided with a bark-mill. The baths are very elegant, and furnished with materials for vapour baths. The daily ration for non-febrile patients is six ounces of meat and half a *foglietta* of wine. The anatomical lecture-room is very beautiful. The cabinet contains a specimen of a double uterus and vagina; and also wax preparations.

Not far from this, in the Lungara, is the Botanical Garden. The plants are arranged according to the Linnæan system, trees in the higher, and shrubs in the lower part. The walls of the botanical lecture-room are covered with figures of plants. In the *Ospedale degl' Incurabili* on the *Corso*, near the *Piazza del Popolo*, there are 300 beds for surgical patients. The surgical *clinique* is under Titucci, for whose use seven beds are appropriated to male and six to female patients. The spacious slaughter-house is

* We purpose giving Mr. Grainger's interesting observations at length, in our next number.

also worthy of notice; it is situated near the hospital, in the direction of the Tiber. A stream of water flows through it, and it is very clean and judiciously fitted up.

Florence.—Two institutions deserve remark in Florence, the one more interesting to the physician, the other to the philosopher. The first is the *Arcispedale di Sta. Maria Nuova*, intended for the practical improvement of the young doctors of the University of Pisa, as this town possesses no hospitals sufficiently large. It is also intended for lectures on every preliminary branch of knowledge, which here, as in the rest of Italy, are gratuitous. The wards of the hospital, which are built in the form of a cross, are extremely clean and orderly; they contain 2000 beds. Dr. Betti is the Director, the well-known Bufalini the Professor of the medical *clinique*, and Andreini of the surgical. Sixteen physicians, in all, are attached to the hospital. Besides his morning *clinique*, Bufalini, like the other professors, gives lectures in the hospital. The *gabinetto patologico*, which was founded in 1824, and transferred hither in 1832, is open twice a day. It is well arranged, and particularly rich in diseases of the bones. Many preparations, which would have been damaged if kept in spirit, have been copied in wax. A small botanical garden is connected with the hospital.

The second institution, the *Museo*, which is usually called *Specola*, from the adjoining observatory, is near the Pitti Palace. Antinori is the director, Amici the director of the observatory, Nesti professor of mineralogy and geology, and Mazzi of zoology and zootomy. Since Nobili's death, the chair of physics has been unoccupied. The richest collections are at the service of these professors, the most celebrated of which is the anatomical cabinet of wax figures, which is open to the public daily from 9 to 3.

Contrary to the almost universal usage of Italy, the government takes care that this collection shall progress with the march of science. Thus the germination of cryptogamic plants, represented according to the microscopic investigations of Amici, has lately been added; and Mazzi is occupied with putting up the shells according to Cuvier's system, and replacing the collection of butterflies, which was much damaged, by a new one. The wax preparations of the zootomical collection are augmented, and the less perfect ones improved, *e. g.* the representation of the development of the chicken in the egg, according to Malpighi.

The physical cabinet, which is particularly interesting, from possessing the tube with which Galileo discovered the satellites of Jupiter, as well as the observatory, contain the newest and most costly instruments.

The hospital of *San Bonifacio*, in the

direction of the *Porta San Gallo*, contains in one division an *hospice* for incurable patients, and in the other a well-arranged lunatic asylum, founded under Leopold II.

The Baths of Lucca are situated two posts from Lucca, in a romantic valley, between shady mountains. The *Bagni di Villa* are the highest spring, the hottest being the *Bagni caldi*, or *Docce alte*, which are of the temperature of 45° of Reaumur, or 133½° of Fahrenheit. There are five bathing houses, to which the water is conducted by leaden pipes; the spring *San Bernabo* alone rises near the new and elegant house belonging to it, which contains nine bath rooms and different apparatus for douches, including ascending ones. Its temperature is 32° R. or 104° F. The *Villa*, which is of the same temperature, contains public baths, one for each sex, bathing rooms, and douches. The fifth house is *S. Giovanni*, whose water, as well as that of the *Villa*, is also drunk. Carini is the official physician of the watering-place, and director of the hospital; he comes here only in July and August, Dr. Derè being resident during the rest of the time.

The Baths of Pisa are situated at the end of the plain in which Pisa lies, four Italian miles from the town, at the foot of the bare and stony mountain, *San Giuliano*. Medically speaking, they are more efficacious than those of Lucca, but they are destitute of every thing attractive. The only walk is a green planted with trees. The springs are an earthy and saline mineral water, the warm one being of the temperature of 35° R., or 110½° F., the cold one 23° R., or 83½° F. Each of the two bath houses, which stand before the pump-room, is supplied by both springs, and possesses two public baths, one for each sex. They contain, together, thirty-six bathing rooms, which for the most part are provided with douches.

Genoa does not belie its epithet of *la superba* in its hospitals, its poor-house, and its university, which are chiefly constructed of marble. The *Albergo dei Poveri*, in front of the *Porta Carbonara*, has beautiful marble stairs; the spacious entrance-hall is adorned with statues of the benefactors of the institution, and is paved with squares of white and black marble, which, in the work-rooms, however, is replaced by bricks in a very bad state. The church is decorated with marble columns, and a bas-relief by Michael Angelo. The institution occupies 1000 women and 800 men. Children are received from their fourth year, and in their fourteenth may resolve whether they will remain there or go out. The girls, when they marry, receive 200 francs as a dowry from the commune. Meat is given three times a week, and wine on Sundays and holidays. There are rooms for the manufacture of wool, silk, linen, cot-

ton and carpet weaving; a ward for slight cases of illness, the more serious ones being removed to the town; and a school for the children. A prize is given yearly to the best workman.

The great hospital *Pammatton*, in the vicinity of the theatre, is a large square, with arcades, supported by marble pillars, around a court paved with marble. A beautiful marble staircase, covered with statues of benefactors, leads to the wards, which are attended by the sisters of Mercy, and where the medical *clinique* is held.

Not far from it stands the *Ospedaletto*, which, in its lower rooms, contains 700 incurable patients, of both sexes and all ages; and 300 lunatics upstairs, in very dirty wards, the furious ones being together, and in chains. For the lunatics a well arranged, but badly situated, asylum is being built in the marshy tract fronting the *Porta dell' Arco*, near the noisy parade. It consists of a round central building, with six wings, in the two lower stories of which are 300 cells; in the third one, halls for walking; and below ground, two dark and padded rooms, eight cells for furious patients, and twelve baths. To prevent accidents the doors are entirely covered with wire lattices, and the stairs up to above a man's height.

In the vicinity of the *Aguasola* walk is the institution for the deaf and dumb, founded in 1818, and now containing 37 pupils, who are instructed in writing, geography, biblical and Roman history, natural philosophy, and religion. The attempt to have the words articulated is not made here. The institution is open to the public from 10 to 12 on Wednesday and Friday, while instruction is going on.

Aix les Bains, or, in *Savoy*, is situated four English miles from Chamberg, and one from the agreeable lake of Bourget. Its warm baths were used by the Romans under the name of *Aquæ Gralianæ*. Aix has two springs; the alum spring, at a temperature of 36° R., or 113° F., rises on the mountain behind the bathing-house; the sulphureous spring, at 35° R., or 110½° F., rises in the building itself. The bath-house contains two mud baths, one for gentlemen, the other for ladies, which are supplied from the aluminous spring; douches; twenty bath-rooms, supplied from both the springs; and sulphureous vapour baths.

S. Gervais is a spring in *Savoy*, near the Arve, in a very romantic district, between the Sallanches and Chamouni. It is of the temperature of 32° R., or 104° F., and contains sulphate of soda. The bathing establishments contain twenty-four bath-rooms, as well as douches. Dr. de Mey is the proprietor and physician.—*Zeitschrift für die gesammte Medicin*.

BLOOD-CORPUSCLES.

THE discovery of the blood-corpuscles by Malpighi was one of the first fruits of microscopic study, and since that event few objects have been more solicitously examined. It is now agreed that they are minute, flattened, transparent cells, containing (at least during one period of their existence) round or oval nuclei, and having incorporated in them all the red colouring matter of the blood.

a. Form and size. They are circular in man and in all mammalia, except the camel tribe in which they are elliptical; and they are elliptical in all other vertebrata, except certain cyclostomes, in which they are circular. In all they are flattened and have rounded borders. Whether their surfaces be slightly concave or convex depends on variations in the quantity of their contents which may ensue either within, or after their removal from, the body. In invertebrata they are less numerous, but more varied in form; for the most part they are irregular, granular, roundish, nucleated corpuscles.

It is difficult to discern any strict connection between the various sizes of these bodies and the other parts of the organism of different animals. Among mammalia those of the elephant are the largest; then come those of the papybara and rhinoceros; then those of man, which have an average diameter of about 1-3500th or 1-4000th of an inch. In general those of ruminants are smaller than those of other mammalia; and the smallest yet known are those of the little chevrotain and Napu musk-deer, of which the average diameter is less than 1-12000th of an inch. An examination of the of elaborate tables by Mr. Gulliver shows that the size of the corpuscles in mammalia is not unconditionally proportionate to that of each animal, or according to the nature of its food. Yet there is evidence enough that in each great division of the class, the size of the blood-corpuscles is, with few exceptions, directly proportionate to that of the animal's body; and that, in general, those of omnivora are larger than those of herbivora; so that if the kind of food and the size of the mammal be known, the size of its blood-corpuscles may be probably estimated.

In birds there is a greater uniformity of size and shape in the blood-corpuscles than in mammalia, and, according to Mr. Gulliver, a nearer relation between their size and that of the body. They are the smallest of the elliptical blood-corpuscles, those of the camel tribe excepted: they are generally rather less than twice as long as they are broad, measuring about 1-2000th by 1-4000th of an inch, and about six times as long as they are thick. In reptiles, the largest and, by comparison, the thinnest, blood-corpuscles

yet known occur; and Wagner remarks it as a general rule, which Mr. Owen confirms, that the longer the branchial apparatus persists, the larger are the blood-corpuscles. Thus, in the *Proteus* they are about 1-350th of an inch long, in the *Syren* 1-435th by 1-108th; in the batrachian reptiles generally, about 1-1000th by 1-3000th; and their thickness is not more than one eighth of their length. This rule, however, fails when one comes to fish, in which the branchial apparatus is persistent and perfect; for in them the blood-corpuscles, though resembling those of reptiles, are generally smaller and less elongated.

b. Structure and Composition. The blood-corpuscles are generally regarded as primary nucleated cells, and no one doubts that those of birds and the lower vertebrata consist of an external cell, formed of an extremely delicate, soft, and elastic membrane, in and within which all the colouring matter seems to be contained, and of an internal parietal nucleus, generally similar in form to the cell, but about one fourth its size, colourless, and in the large corpuscles of some of the amphibia containing a number of distinct granules.

It is questioned, however, especially by Valentin, Wagner, and Gulliver, whether the corpuscles of mammalia have nuclei, or whether the central spot be not merely produced by the accumulation of the colouring matter at the circumference. Henle would decide the question by saying that, in a few of these small corpuscles, there are nuclei; but that in the majority, (and these the most fully developed,) there are none; so that he thinks it probable, that here, as in some other cases, the nucleus, after the cell is perfected, is gradually absorbed.

According to Dr. Barry, the young blood-corpuscle in all the vertebrata is a mere disc, with a depression in the centre. In mammalia it retains this form; in the other classes the disc becomes a nucleated cell. The nucleus at first communicates by a pellucid orifice ("nucleolus") with the exterior of the corpuscle, this orifice occupying the place of the depression in the original disc. The orifice becomes narrower, and the nucleus finely granular, and these changes immediately precede the division of the nucleus into minute discs. The discs, whose number is multiplied by successive divisions and gradual appropriation of the nucleus from its circumference towards its centre, arrange themselves so as to form a flat filament, having an appearance the same as that which he finds to be presented by fibre in all the filamentous structures of the body. According to the number of discs, this filament forms within the blood-corpuscle either a ring (as in man and most mammalia, where there are comparatively few), or a coil (as in birds, amphibia, and

fishes, where the discs are much more numerous, and the filaments proportionally longer.)

The filament thus formed is flat and deeply grooved on both surfaces, being thereby thinner in the middle than at the edges. The edges are rounded; and when seen on its edge, the filament at first sight seems to consist of segments separated from one another by oblique lines. When perfected, the filament undergoes various changes: sometimes unwinding itself into a straight fibre; at others, continuing circular, while smaller coils of similar filaments are formed within it from a residual portion of the nucleus. In all cases the filament is reproduced by self-division, so that out of a single filament a fasciculus may be formed. Such changes are seen going on in coagulating blood. The filaments now mentioned exactly resemble those which are found in a great many both animal and vegetable tissues, nor can any definite line of distinction be drawn among the gradations from them to the double spiral filament, of which Dr. Barry believes that the primitive fibrils of muscle, and certain other tissues, are composed.

In all cases in which a nucleus is present, it differs in chemical characters from the cell. The colouring matter, or hæmatosine, is easily soluble in water, by which it may be completely washed out of the enveloping cells. The latter are composed of a peculiar albuminous substance (*globulin* of Berzelius), which only slowly dissolves in water; the nuclei consist of a different albuminous substance, more like coagulated fibrine, which is quite insoluble in water, and they contain so large a quantity of inorganic matter, that they completely retain their form, and, apparently, their substance after combustion.

Purpose. Dr. Barry's and others' facts make it nearly certain that the blood-corpuscles take an important part in nutrition, if not in providing the materials of the tissues ready formed, yet in giving them their due capacity for development. In some cases of reparation, indeed, as of fractured bones, the Hunterian opinion that the effused blood becomes the bond of union is strengthened by the knowledge of the changes which the blood-corpuscles may undergo; but the present evidence is insufficient to make it probable that they, or any formed parts of them, are effused in ordinary nutrition. Wagner and Henle suppose that during all their circulation, the blood-corpuscles, by the energy which they like other primary cells may possess, are occupied in giving to the blood the constitution necessary for nutrition, secretion, &c. And this seems highly probable. It is not so reasonable, for example, to suppose that the effects of respiration are finished in the lungs, as to believe that the influence of the oxygen dissolved in

the blood, is accomplished during the general circulation, through the medium of these cells with which it is continually in contact, and which might be compared to floating gland-cells.—*Mr. Paget's Report on the Microscope.*

M. DE RENZI ON TYPHUS FEVER.

AN epidemic of typhus fever, which occurred in March and April, 1841, forms the object of this memoir. The disorder raged with great severity. The most severe and frequent phenomena were those of affections of the brain, the malady at its commencement sometimes assuming the character of apoplexy.

M. de Renzi took advantage of this opportunity to pursue his researches into the composition of the blood in typhus, and the following are the results of his investigations in a large number of cases. He agrees with Andral and Gavarret—1. That the clot is usually soft and oleaginous. 2. That the fibrine is in smaller quantity than in healthy blood. 3. The globules are increased in quantity. 4. The cruor is readily dissolved in the serum, colouring it red, and being precipitated from it in the form of a powdery sediment. The hematosine has little coherence with the globules and the fibrine.

In addition to these observations already advanced by the French physicians, M. de Renzi adds other equally important characters. Thus, in addition to the increased quantity of globules, and their easy separation from the colouring matter, they appear to be deprived of their central nucleus, and seem less compact, less solid, and, so to speak, less alive. In the second place, there exists in the blood during typhus fever a peculiar odour, as if it had undergone the commencement of putrefaction.

In spite of the occurrence of all these alterations, M. de Renzi does not profess that the cause of typhus fever exists uniformly in a change in the composition of the blood; this is regarded by him as only one of a great train of symptoms. We must equally take into account the nervous lesion characterised by stupor and muscular prostration, as well as the alteration in the intestinal mucous membrane.

M. de Renzi considers these researches into the composition of the blood in typhus to give a satisfactory explanation of many of the phenomena occurring in the course of this disorder. We know that M. Magendie found hæmorrhages and congestions to occur in animals in proportion to the degree in which he diminished the quantity of fibrine in their blood; and M. de Renzi thinks we may, by analogy, attribute to the

elimination of fibrine in the blood during typhus the following symptoms, which are of so frequent occurrence:—1. The tendency to congestions in different organs, which scarcely bear the name of inflammations. 2. The hæmorrhages and effusions of blood into internal cavities. 3. Small interstitial sub-epidermic and submucous hæmorrhages, forming spots, suffusions, petechiæ, &c.—*Il Filiale Sebezio; and Gazette Médicale.*

MICROSCOPIC CHARACTER OF THE SPUTA IN PHTHISIS.

M. SANDRAS read before the Academy of Medicine a paper on this subject. He considers the results of repeated microscopic examination of the sputa in phthisis, to confirm the idea of their possessing a specific nature, and furnishes an important means of diagnosis. These researches possess, moreover, the advantage that, in their repetition, they require no particular care or dexterity.

He discovers in the sputa of phthisis numerous globules, rounded, separated from one another, of a greyish-white colour, corresponding in size and shape with the globules of pus, but differing, inasmuch as the latter are usually circumscribed, whereas the former are covered on their surface by a flocculent layer not separable by washing. Another peculiarity in these globules is, that they are nearly opaque at the centre, and gradually become more transparent towards the circumference.

All phthisical patients, however, do not expectorate sputa of this nature; neither do all the sputa from the same patient present similar characters. This is not to be wondered at, inasmuch as the source of the expectorated matter varies, sometimes consisting of pus from a tuberculous cavity, at others being mixed with bronchial mucus.

It is, moreover, remarkable that these globules cannot always be detected in the pus derived from tuberculous glands and in intestinal ulcerations of the same nature.

The author remarks that he has repeatedly examined the sputa in cases of simple catarrh, and found them to correspond with those from phthisical patients, with the exception of the globules. They presented only corpuscles differing from the phthisical globules:—1st, in that they were not separated from one another; 2d, they had not all the same size; 3d, they frequently disappeared under the microscope; 4th, they were striated on their surface.

In spite of the distinguishing characters, the author remarks that there are many cases in which it is difficult to form a deci-

sion, and these especially where the physical signs and the course of the disease appeared to contradict the indications afforded by the microscope. In general, however, the autopsy gave confirmation to the microscope.

PROPERTIES OF VEGETABLE ALBUMEN.

As the organic arrangement of the ultimate vegetable tissue presents some analogy to that of animals, so do their secretions. Vegetable albumen is identical with animal albumen (white of egg, albumen of the blood); tained gluten is analogous to caseum, and the starch contained in the cells of the potato resembles cellulin in the closest manner. Inuline, and immediate principle contained in the cells of the dahlia, iuula helenium, &c., is analogous to fecula; cane sugar is contained in the beet root; raisin sugar in the mallocoi of many sweet fruits; finally, different colouring matters, the fixed and essential oils, vegetable alkalis, and even the mineral salts, are enclosed in the ultimate tissue of the vegetable kingdom. Thus, plants secrete not only the vegetable alkalis, but likewise contain mineral alkalis and salts, which they have derived from the bosom of the earth, and which we separate from them by incineration.

The vegetable albumen, which is contained in such large quantities in vegetable tissues, and performs functions analogous to those of the mucous membrane in animals, communicates to the ligneous cells (and consequently to wood) the aptitude of taking on the dry or moist putrefactive process; for this albumen is an azotised substance, and identical with an animal matter which is in the highest degree prone to putrefaction. The absence of albumen, and the compactness of the ligneous fibres in acacia wood, explain why it remains sound under circumstances which destroy every other kind of wood.—*Provincial Medical Journal.*

ON INJECTIONS INTO SEROUS CAVITIES.

For some time back M. Velpeau has devoted his attention to the effects of injections into different serous cavities: a few of the results he now mentions. He makes a small puncture into the cavity and injects a solution of iodine; in this way he has effected a cure in cases of serous cysts, sanguineous cysts, and colloid cysts, in almost every region of the body. Bronchocele often consists in cysts filled with a serous or dark fluid; in

five cases of this kind the author tried the iodine injections, and was completely successful. In dropsy of the articular cavities the operation would seem to be more dangerous. M. Velpeau tried this plan in two cases; one was cured, but in the other case it did not succeed; but he has recently employed a more simple mode of operating in cases of hydrarthrosis, and the results lead him to hope that it will be as easy to cure this disease as hydrocele with iodine injections.—*Ibid.*

SKATE-LIVER OIL

PREFERABLE AS A THERAPEUTIC AGENT
TO COD-LIVER OIL,

THE disagreeable odour and taste of cod liver oil has, it would appear, led to the substitution of the oil obtained from the liver of the skate (*Raja clavata* and *R. batis*) in place of it. In Holland and Belgium this oil is preferred to that of the cod, as being both less disagreeable to the taste internally, and also fully more efficacious in its therapeutic effects. MM. Girardin and Preisser were therefore induced carefully to analyze it, and found it to contain a per centage more of the ioduret of potassium than the cod-liver oil, whilst, in point of purity and other properties, it appeared to be superior to it. They therefore recommend it as a valuable substitute for the more nauseous article at present in use.—*Journal de Pharmacie: Edin. Med. and Surg. Journal.*

NON-RESTRAINT SYSTEM.

To the Editor of the Medical Gazette.

SIR,

ALTHOUGH I am anxious to disabuse the public mind of an impression studiously and dexterously circulated, both in this kingdom as well as in foreign parts, that the practice of the non-restraint system, and occupation of the insane patients at Hanwell, are exclusively confined to that establishment, still I have no desire to puff myself into notice; neither am I disposed to detract from the high merit which is due to Dr. Conolly for his humane and judicious treatment of the insane. But much having been said on the non-restraint system, and occupation of the patients there pursued, I consider it due to my own reputation—due, also, I have no doubt, to many other well-conducted establishments—to state most distinctly, that the non-restraint system has been carried out for more than *thirty years* at the *Laverstock Asylum*, under my direc

tion, and with the same salutary and practical results as at Hanwell, never more than from one to three patients per cent. having been under restraint at any one period. A reference to the "Visitor's Books," to Dr. Thomas's celebrated work on the Practice of Physic, published nearly twenty years ago, who states (from his personal observation) the almost *total absence of personal restraint* of the patients, and the varied amusements and occupations provided for them; and also to the following evidence recorded before the Committee of the House of Commons, as far back as the year 1815, will establish this fact.

"On the 25th Sept. 1815, I called upon Dr. Finch, at Laverstock, near Salisbury. This gentleman conducts his house in an admirable manner. He has 120 patients, and he begged me to take time to converse with the whole of them, without his being present, to ascertain how they were fed and treated. He had not a *single patient in a strait waistcoat*, or under *any personal restraint*. Every possible kind of amusements was provided for them: billiards, backgammon, chess, cards, books, drawing &c., in-doors; bowls, cricket, horses, carriages, and varied exercises and occupations out of doors. In this establishment I saw all that Tuke had written realised; and no words in which I can describe it can characterise it in too high terms."—I am, sir,

Your obliged servant,

W. FINCH, M.D. F.L.S.

Laverstock House Asylum, Salisbury,
October 20, 1842.

DEAFNESS SUCCESSFULLY TREATED AND CURED

BY MEDICATED VAPOUR DOUCHE, AND
THE MEATUS EXTERNUS DILATED
BY TENTS, &c.

To the Editor of the Medical Gazette.

SIR,

SHOULD you deem the enclosed interesting case deserving a place in your respectable and invaluable journal, I should feel obliged by its insertion,

I am, sir, yours respectfully,

WILLIAM THORNTON,

Army Surgeon, and M.R.C.S.L.

31, Baker Street, Portman Square,
22d Oct. 1842.

A gentleman residing in London, of general good health, but of a nervous temperament, has been deaf twenty-three years, in consequence of frequent colds; but his hearing was so defective as to render his life almost a burden to him. He had applied to

several (so styled) aurists, &c. who had prescribed stimulating oils, lotions, and blisters, without benefit. Upon examination of the meatus auditorius externus of the right ear, I found it was much contracted in its calibre, by the thickening of the surrounding parts, and especially the greatly increased density of the cuticle, which had a white rosy appearance, extending to the bottom of the auditory canal (near the insertion of the membrana tympani). On injecting warm water, a dull obtuse sound was produced, as if some dense medium was interposed; (the patient said that he felt something rattle in his ear). The orifice was nearly closed, and it was with some difficulty that a probe entered it. A sensation to my touch was conveyed different from that which would have been produced by the contact of a healthy membrane; whilst, at the same time, it did not cause the usual painful sensation. The sense of hearing was nearly lost, but my watch applied to the ear was audible. He could with difficulty force air into the tympanum by powerful expiration. The nose and mouth being closed, air passed freely through the left Eustachian tube into the outer ear, the membrana tympani being perforated. The patient was not conscious of this circumstance. On passing the catheter into the Eustachian tube, it was clearly shown to be narrowed; the air-douche passed with some gurgling noise into the tympanum, and in the left tube the air passes freely; hearing distance of this ear was six inches. On syringing the meatus, and dilating the orifice, there was not the slightest appearance of cerumen, but the same rosy white thickened cuticle appeared to extend as far as the eye could reach. These circumstances led me to think that it was possible the deafness depended on a thickened state of the cuticle reflected over the membrana tympani, similar to that which lined the meatus, or some morbid secretion existing between this cuticular layer and the membrane. To remove this cuticular lining I used a strong solution of acetate of zinc. In a few days, upon syringing with tepid water, several dark pieces of cuticle were washed out, and the orifice dilated so much as to give a clear view of the state of the membrana tympani, which appeared dull and dry. The unpleasant noise the patient had formerly complained of was now removed, and from this time his hearing daily improved, to the great delight of the sufferer.

The medicated vapour douche used daily. After several sittings, the vapour passed freely into the tympanical cavities, and his hearing gradually increased. The contraction was dilated by tents, and the auditory passage anointed with Ung. Hydrarg.; Nitrat. dilut., and Ung. Iodidum Comp.

rubbed behind the ear, and on the mastoid cells; at the same time, Deut. Sarsæ. concentrated with Potassæ. Iodidum, administered. Under this treatment for six weeks, his hearing functions were restored and cured.

P.S. This gentleman had been under the treatment of an aurist five months, without receiving any benefit, and said that his deafness was increased.

LECTURES

ON THE

THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE IV.

*On the Physiology of the Unimpregnated
Uterus and its appendages.*

At the age of maturity, when the uterine system is fully developed, menstruation commences. The appearance of the discharge from the uterus is usually preceded by constitutional disturbance, sense of weight within the pelvis, pain in the back and loins, and other symptoms of congestion of the blood-vessels of the uterus, and irritation of its whole nervous system. These subside as the catamenia or menses flow; and in some women they are so slight as scarcely to be observed. The discharge takes place every four weeks, or lunar month, and lasts two, three, four, five, or more days, and is accompanied by the detachment or exfoliation of the delicate epithelium of the mucous membrane of the uterus, which is soon reproduced. In some it continues only two days, in others three, and in a few eight or even more. The usual period is from three to six days; the largest quantity escaping on the second and third; and it most frequently returns at intervals of three or four weeks. The intervals between the periods of menstruation are, in some, invariably the same; in others they are unequal by several days. Its periodical return is accompanied frequently with the local and constitutional symptoms described.

It is difficult to ascertain the precise
779.—XXXI.

quantity of menstrual fluid which is discharged at each period. It probably varies from three to six ounces; but the same persons have often more at one period than another; and there is a great difference observed among women, not only in the quantity, but in the duration of each menstrual period, and the length of the intervals between them.

The fluid has a red colour, like blood; in some florid, like arterial blood; and in others of a darker colour, like venous blood. In the healthy condition blood corpuscles can be detected in it. It contains much less fibrine than blood, and does not generally coagulate, nor become decomposed when preserved for any length of time. Professor Brande analysed the menstrual fluid once; and he says it has all the properties of a very concentrated solution of the colouring matter of the blood, in a diluted serum. It was fluid which had long been accumulating in the vagina. Gmelin states that it contains no globules, is green by transmitted light, and resembles a strong solution of the colouring matter of the blood in serum. In a case where the fluid had been retained for some time by an occlusion of the vagina, it appeared as a thick, glutinous, reddish-brown syrup, without any smell: three days' exposure to the air produced no change in it; there was no deposit or coagulum, nor any approach to putrefaction: it was liquified by potash, and thickened by sulphuric acid and alcohol: water, in which it was immersed, took very little of its colour, but subsequently became clouded by evaporation, and as if coagulated on the action of alcohol. About two years ago I saw a similar case of occlusion of the vagina, in which a quantity of fluid similar to that now described had accumulated; but, on being kept for some days, it became decomposed as blood would have done. I believe we are still in want of a good chemical analysis of healthy menstrual fluid. One thing respect-

M

ing it is certain, whatever its chemical composition may be, that it has none of the irritating noxious qualities which were attributed to it by Pliny, Columella, and some modern writers. Galen knew that it proceeds from the inner surface of the uterus, and that it is different from blood. In cases of prolapsus of the uterus, it has been seen flowing from the os tinæ, and from the lining membrane where the uterus has been inverted. "In a natural evacuation of blood, viz. menstruation," says Mr. Hunter, "it is neither similar to blood taken from a vein of the same person, nor to that which is extravasated by an accident in any other part of the body; but is a species of blood changed, separated, or thrown off from the common mass, by an action of the vessels of the uterus similar to that of secretion; by which action the blood loses the principle of coagulation, and, I suppose, of life." Most physiologists have adopted this view of menstruation, and consider it as a peculiar function of the lining membrane of the uterus, analogous to secretion.

It has been stated by almost all writers, that women reach maturity, and that menstruation commences, much earlier in hot climates, particularly between the tropics, than in temperate and very cold countries. Haller states, that in the warm regions of Asia, the catamenia appear from the eighth to the tenth year; and in Switzerland, Britain, and other temperate regions, at the age of twelve or thirteen, and later the farther we ascend towards the north. The same view is taken by Denman, Burns, and Dewees, who have inferred that, like plants, animals reach maturity sooner in hot than cold countries. Dewees says menstruation occurs later in the northern than southern States of America.

"The early or late appearance of the menses," observes Dr. Denman, "may depend upon the climate, the constitution, the delicacy or hardness of living, and upon the manners of those with whom young women converse. There seems to be an analogy between the effect of heat upon fruits and the female constitution, with respect to menstruation; for the warmer the climate, the sooner the menses appear. In Greece and other hot countries, girls begin to menstruate at eight, nine, and ten years of age; but, advancing to the northern climates, there is a gradual protraction of the time till we come to Lapland, where women do not menstruate till they arrive at maturer age; and then in small quantities, at long intervals, and sometimes only in the summer." Müller repeats this in the last volume of his *Physiology*.

Mr. Robertson, of Manchester, has pub-

lished, in the North of England, and Edinburgh Medical and Surgical Journals, several elaborate and extremely interesting papers, containing numerous facts to prove that, in this country, the natural period of puberty in women occurs in a much more extended range of ages, and is more equally distributed through that range, than authors have alleged; and that, in other countries, the parallel between plants, fruits, and the female constitution, does not hold good. The following table shews the ages at which 450 women began to menstruate in Manchester:—

10 at 11 years of age.	
19 — 12	"

In five sisters it commenced at eleven, and one was a mother at 12: rendering it probable that the period of puberty depends on constitutional and probably hereditary peculiarities.

The following table, shewing the ages at which eleven hundred women began to menstruate in London, corroborates the preceding statements respecting the extended range of ages in which puberty occurs:—

11 began to menstruate at 9 years of age.

At Göttingen, Osiander ascertained the ages at which 137 women began to menstruate. In 21 of these the catamenia first appeared at 14; in 32 at 15; and in 24 at 16 years of age. Nine began at 12, and one not before the 24th year.

In 77 women observed by Mr. Robertson, 1 ceased to menstruate at the age of 36: 4—40: 1—42: 1—43: 3—44: 4—45: 3—47: 10—48: 7—49: 26—50: 2—51: 7—52: 2—53: 2—54: 1—57: 2—60: and one at the age of 70.

Of 132 women in London, I ascertained with certainty that menstruation ceased in—

1 at 22 years of age.

Mr. Robertson has collected together many facts which tend to prove that, in other countries, there is no parallel between plants and the female constitution. He quotes passages from the travels of Hearne, Back, Lyon, and Dr. Richardson, to prove that the North American, Cree Indians, Copper Mine Indians, and Esquimaux, frequently begin to menstruate at twelve, thirteen, and fourteen years of age. From the statements of Baron Humboldt, the same is equally true of the Korriacs, and the tribes of Northern Asia, where girls of ten years are sometimes found mothers. The notion that women in Lapland do not menstruate till twenty, and only in summer, is founded on a mistake committed in the translation of the following passage in Linnæus's "*Flora Lapponica*." "*Hoc etiam musco catamenia excipere abstergereque feminas lapponicas mihi relatum fuit. Naturam æque hic ac alibi sibi similem esse, feminasque in Lapponia legibus menstruorum similibus obedire: dubium nullum est, licet hæ cruoris minorem fundant copiam innocentissimè. Fuere et feminæ plures hic quas vidi, per totam suæ vitæ periodum, ab hac lege exceptæ, licet hæ maritatæ steriles persistant. Novi et juvenulas quæ non hyme, sed solâ modo æstate has observabant crises: imo et alias, quæ semel in anno purgabantur, et hæ, quot quot vidi, pedes oedematosos habebant.*" Tooke states that the Slavonian or native Russians reach puberty at an early age, at their twelfth or thirteenth year; and that the same is the case with the Samoiedes, Korriacs, and Kamschatdales. In the Crimea, and in all

the Russian provinces along the Black Sea, and in the Ukraine, I had good opportunities, during three years, of ascertaining the period when menstruation usually commences and ceases, and all the derangements to which this function is liable, in the higher and lower classes; and my conviction is, that over the whole South of Russia, the usual period of puberty is the same as in Great Britain, and that women cease to bear children at the same age. Mr. Robertson refers to the works of Mr. Crawford and Sir Stamford Raffles for proofs that the same is the case in Java, and in all the islands of the Indian Archipelago; and that the body continues to grow there as long, and that women bear children to as late a period of life, and that longevity is as frequent as here. From the statements of Dr. Winterbottom, the same is the case with Sierra Leone. Mr. R. thinks that the early marriages, and the universal licentiousness and depravity of morals which reign in Arabia, will account for any difference observed in that country.

Mr. George Babington, Surgeon to St. George's Hospital, has informed me, from an examination of documents at the Statistical Society, that the period of puberty in the island of Grenada is the same as in this country; and Mr. Young, formerly a pupil of this class, and now in the West Indies, has communicated to me the same fact with respect to the island of Barbadoes.

In the 152d vol. of the Edinburgh Medical and Surgical Journal, which has recently appeared, and in the MEDICAL GAZETTE, vol. xxx. p. 677, Mr. R. has published a paper on the period of puberty in negro women, and has given a table from Jamaica, from which it appears that in 12 negresses the menses appeared in one aged 16: 3—15: 3—14: 3—13: and in 2 aged 12 years. It is stated by the Reverend Messrs. Elliot and Harvey, who communicated this information, that they could have added many cases of negresses from 8 to 11 years of age, in whom there is as yet no menstrual appearance.

Dr. Nicholson, of St. John's, Antigua, states after being 19 years in the island, with extensive opportunities for accurate observation, that he has never met with a case of menstruation before the 12th year, either in whites or blacks, but he has met with a few cases at that age both in whites and blacks and in the mixed race; that such cases are rare is proved by the fact of his having been consulted professionally on account of that circumstance. He states further that menstruation commences most frequently in the 14th and 15th years, and that no difference exists in this respect between blacks and whites, but cases of tardy menstruation from chlorosis are more frequent with the latter. This he does not attribute to any constitutional

difference existing in these races, but to local causes affecting the individual ; such as miasmatic effluvia, to which the blacks are more exposed. Dr. Nicholson adds that he has never met with a case of pregnancy before menstruation, but that irregular monthly discharges during pregnancy, in every respect resembling the catamenia, are not unfrequent occurrences in Antigua, particularly with white females of a sanguine temperant.

It is, however, right to state, that some gentlemen who have resided many years in the East Indies, the Brazils, and on the coast of Africa, with whom I have conversed on this subject, and who have had good opportunities for observation, are of a contrary opinion, and still firmly believe that the period of puberty is earlier between the tropics than in Europe. As none of them investigated the subject, I think, with the requisite care, their evidence can have little weight when contrasted with the great mass of facts now adduced to support the opposite view. It has been stated that women who have been born in the East Indies, and who have been sent to England at an early age, begin to menstruate before the usual period, in this country. I have seen a considerable number of cases which prove that there are numerous exceptions to this.

Menstruation is suspended during pregnancy, and generally during suckling, for six, eight, or ten months, or longer : some pregnant women have periodical discharges of blood from the uterus, but regular menstruation is rarely if ever observed during utero-gestation. I have never seen an unequivocal example of it, and Dr. Denman, in the course of his long experience, never met with a case. In some children whose uterine system has been prematurely developed, menstruation has commenced at a very early period of life, and it has then sometimes been accompanied with chorea or hysteria.

The function of menstruation is peculiar to the female of the human species, and from the earliest historical records of our race, it is known that this function was performed periodically in the most remote ages as it is at the present time. The first appearance of the catamenia at the age of puberty, its suspension during pregnancy and lactation, and its cessation in advanced years, are circumstances which prove that it is intimately connected with the process of reproduction.

Some physiologists think that menstruation puts or preserves the uterus in a state fit for impregnation ; but the function is never performed unless the uterus is previously in a healthy condition. It might be affirmed with equal truth, that the secretion of bile puts or preserves the liver in a healthy state ; the urine the kidneys ; and the gastric fluid the coats of the stomach. That the uterus can be in a fit state for conception without menstrua-

tion is proved by this fact—that some women have become pregnant who have never menstruated, and many have conceived during suckling who have not menstruated since their previous conception, or even during successive pregnancies and the intervals of suckling.

Some have attributed menstruation to the influence of the moon, to the upright position of women, to the presence of an undue proportion of azote in the blood of the uterus, fermentation of the blood, sexual desire, and many other hypothetical causes. It has been referred, with greater reason, since the days of Aristotle, to a periodical plethora of the vessels of the uterus—a molimen, irritation, or effort, of the uterine system every month, but no adequate cause has been assigned for this. The sensations usually experienced at the time the catamenia are present, and the examination of the bodies of those who have died from disease during menstruation, prove that the uterine arteries and veins are then distended with blood. Blood is not unfrequently extravasated with the catamenial fluid, and if the uterus be examined during the monthly period, it is usually found to be larger and heavier than during the intervals of menstruation. That something more than a mere determination of blood to the uterine system is required for menstruation will appear from the fact that suppression of the catamenia is not unfrequently produced by unusual congestion of the uterine vessels, and that the obstruction is removed by local abstraction of blood.

That the determination of blood which takes place to the uterine system every month, and that all the phenomena of menstruation, depend upon the ovaria, and that at each period a Graafian vesicle bursts and its contents escape, is rendered extremely probable by the following facts.

If the ovaria are wanting, or removed artificially, or have their healthy structure destroyed by disease, menstruation either never commences or it entirely ceases. The case of a young woman who died at the age of 29, in whom the ovaria were wanting, was published by Mr. Charles Pears, in the *Philosophical Transactions* for 1805, and the following appearances have been recorded. " Having ceased to grow at ten years of age, she was in stature not more than four feet six inches high. The breadth across the shoulders was as much as fourteen inches, but her pelvis measured only nine inches from the ossa ilia to the sacrum ; her breasts and nipples never enlarged more than in the male subject. She never menstruated, there was no appearance of hair on the pubes, nor were there any indications of puberty in mind or body, at twenty nine-years of age."

In the young woman whose ovaria were extirpated by Mr. Pott, in an operation for

inguinal hernia, the voice became hoarse, the mammae shrunk, and hair appeared on the chin and upper lip. Before the operation, this female was stout, large-breasted, and menstruated regularly.

Menstruation disappears if the structure of both ovaria be destroyed by any disease. In ovarian dropsy, if one ovary only be affected, menstruation continues until the powers of the constitution are greatly impaired, but if the disease exists in both ovaria from the beginning, the function is soon interrupted. The same effect is produced if the structure of the ovaria be disorganized by any other disease. A woman, aged 21, died in 1836, in St George's Hospital, from tubercular phthisis, and both ovaria and fallopian tubes were completely changed by scrofulous disease. She never menstruated, and the uterus was like the uterus of a child, with a long neck and small body. In many young women who die of chronic disease, the ovaria are flaccid, and extremely small. Something not very dissimilar to these effects in the human subject when the ovaria have been removed, has been observed by Mr. Yarrell in birds. He has shewn that where there is a shrinking and shrivelling of the ovaria from disease in young birds, the hen bird, in many instances, assumes the plumage of the male. Thus, in several mules (hen birds with male plumage) the ovarium has been found variously diseased: sometimes the oviducts appear to have been inflamed, and adhesion to have taken place between their opposite sides, so that they become obliterated; at other times the ovaria are shrivelled, and of a black colour, and appear as if they had never been in progress to maturity. This black colour also pervades the oviduct, which is smaller than natural, and often impervious in some part. In old birds it might fairly have been alleged that the destruction of the ovarium and the change of plumage followed only the general obliteration induced by age, and that the one was not dependent on the other: but the fact that destruction by disease of the ovarium, in the young bird, induces a similar change, and the destruction of the oviduct by art, being followed by an alteration, incomplete indeed, but, in many respects, resembling the one mentioned, sets the question at rest.

In cases where the uterus has been wanting, and the ovaria have been present and fully formed, women have usually experienced violent pains within the pelvis every month, and all the symptoms of menstruation have been present except the discharge.

In 1831, I saw a case, with Dr. Girdwood, in which there appeared to be a deficiency of the uterus, and an effort at menstruation every monthly period. The woman was 25

years of age, and had been married two years, though she had never menstruated. Every month there was great pain in the region of the pelvis, which lasted for several days, and then went off, without any menstrual discharge taking place. The mammae and external sexual organs were fully developed. On examination at the posterior part of the vagina, the finger readily passed into a short cul de sac, about an inch and a half in length, but there was no uterus above.

Dr. Stein related a case several years ago to a Medical Society in Berlin, of a married lady, æt. 24, well formed, and the mammae fully developed, whose vagina was found imperforated; and in performing the necessary operation, no uterus could be discovered, but its place was supplied by a soft mass of cellular tissue. She had never menstruated, though there was a regular effort at each catamenial period. Other cases similar to these have been recorded by authors. One very distinct case of this kind came under the observation of Dr. Elliotson and Mr. Cline; there was no uterus, but there was excruciating pain about the pelvis every month: the ovaria had certainly been developed.

On the 11th of March, 1831, I examined the body of a young woman who died, during menstruation, from inflammation of the median basilic vein. The left ovarium was larger than the right, and at one point a small circular opening, with a thin irregular edge, was observed in the peritoneal coat, which led to a cavity of no great depth in the ovarium. Around the opening, to an extent of three or four lines, the surface of the ovarium was of a bright red colour, and considerably elevated above the surrounding part of the peritoneal coat. On cutting into the ovarium, its substance around the opening and depression was vascular, and several Graafian vesicles, of different sizes, were observed. The right ovarium was in the ordinary state. Both fallopian tubes were intensely red and swollen, and their cavities were filled with what appeared to be menstrual fluid. The lining membrane of the uterus was coated with the same fluid, and the parietes were soft and vascular. The size of the uterus was not increased. I pointed out this opening in the peritoneum of the ovary, which I accidentally observed, to Dr. Girdwood and Dr. Prout, and suspected that there was some relation between this and the state of the uterus. At this time I had not seen the human ovum in the Graafian vesicle before impregnation, and was not then aware that cicatrices are never present on the surface of the ovaria before menstruation has commenced.

In the autumn of 1831, Dr. John Prout saw a woman, under 20 years of age, who died suddenly from acute inflammation of

the lungs while menstruating. He examined the body, and brought the uterine organs to me, having taken the greatest care that they should not suffer from any force during their removal from the pelvis. A red, soft, elevated portion of the right ovary was also here observed, and at one part the peritoneal coat, to a small extent, had been removed. The edge of the opening was extremely thin and irregular; and in the substance of the ovary, under the opening, was an enlarged Graafian vesicle, filled with transparent fluid. Numerous small blood-vessels were seen running along the peritoneal coat of the ovary to the opening. When the substance of the ovary was laid open, several vesicles, of various sizes, and at different depths, were found imbedded in it. The left ovary presented a natural appearance. The free extremities of the fallopian tubes were gorged with blood. Their cavities were filled with a red-coloured fluid. The uterus was not enlarged, but the parietes were unusually full of blood, and the lining membrane of the fundus was coated with menstrual fluid. A small coagulum of blood likewise adhered to the upper part of the uterus. I now felt convinced that there must be some connexion between this state of the ovaria and menstruation, and mentioned the facts to Sir Astley Cooper.

On the 2d of July, 1832, Sir Astley sent me the ovary of a woman who died from cholera while menstruating. The ovary was much larger than natural, and at one point there was a small irregular aperture in its peritoneal coat, through which a portion of a slender coagulum of blood was suspended. On cutting into the substance of the ovary it was found to be occupied with three small cysts or cavities, one of which was filled with a clear ropy fluid, another with semi-fluid blood, and the third, which communicated with the opening in the peritoneal coat of the ovary, with a firm coagulum.

On the 18th of November, 1832, Dr. Girdwood and Mr. Webster removed the uterine organs from the body of a young woman who had died suddenly the preceding day, when the catamenia were flowing. Both ovaria were remarkably large; and both fallopian tubes were red and turgid. The peritoneal coat of the left ovary was perforated, at that extremity which was nearest to the uterus, by a circular opening, around which aperture, for several lines, the surface of the ovary was slightly elevated, and of a bright scarlet colour. The margin of this opening was thin and smooth, and did not appear to have been produced by any external force. Its centre was slightly depressed below the level of the edges, but there was scarcely the appearance of a cavity beneath. The right ovary was much

larger than the left; and when cut into, a cyst or cavity was seen filled with half coagulated blood. The peritoneal coat of the ovary was entire. The uterus was large, and when cut into appeared to contain an unusual quantity of blood. The inner membrane was of a bright red colour, and coated with a thin layer of catamenial fluid. Both fallopian tubes were red and turgid, and the interior of the left was filled with menstrual fluid. The appearances now described have been very accurately represented by Mr. Joseph Perry in this drawing [exhibiting it], which was made from the parts in the recent state.

On the 14th of January, 1837, a woman, thirty-seven years of age, who had long suffered from hysteria, died suddenly in St. George's Hospital, during menstruation. No morbid appearance was found to account for her death. A small circular aperture was observed in the peritoneum of the left ovary. This opening communicated with a cavity in the substance of the ovary, which was surrounded with a soft yellow substance of an oval shape. In the preparation [exhibiting it] you see the aperture in the peritoneal coat of the ovary, and the cavity with which it communicates. This aperture would probably not have been detected if the parts had not been covered with pure water.

On the 31st of May, 1841, Mr. A. Shaw was present at the inspection of the body of a woman who died during menstruation in the Middlesex Hospital. In the right ovary, he says, the appearance was presented of one of the Graafian vesicles having been recently ruptured. A part of the surface, of the size of a fourpenny piece, was distinguished by a dark stain upon it; and here the peritoneal coat was slightly elevated, and the ragged edges towards the centre of the stained spot were of a particularly black colour.

In Dr. Gendrin's *Traité Philosophique de Médecine Pratique* (1839) there is a description of the same state of the ovaria in five women who died during menstruation. In the first the left ovary was vascular, and in the middle was an aperture about a line in diameter, with an irregular margin. Its cavity would have contained a hemp seed, its walls were red, and it was obviously a ruptured Graafian vesicle. In the second case a small circular ragged opening led to a cavity two lines in diameter, the walls of which were of a bright red colour. In the fourth the right ovary had an aperture a line and a half in diameter, leading to a small cavity, with vascular walls. M. Negrier has given an account of similar appearances in the ovaria during menstruation, and in this figure [exhibiting it] has represented the ovary of a young woman who died

eight days after the catamenial period. It resembles exactly the drawing on the table, without the colouring. A warm controversy has been carried on between M. Negrier and Dr. Gendrin on the priority of the discovery, and they appear to have been wholly unaware, which adds much to the importance of their observations, that an account of precisely the same appearances had not only been published, seven years before, in the 2d Vol. of the *Cyclopædia of Practical Medicine*, but fifty-eight years before in the *Philosophical Transactions*, by Mr. Cruickshank. "I also have in my possession the uterus and ovaria of a young woman," he observes, "who died with the menses upon her: the external membranes of the ovaria are burst at one place, from whence I suspect an ovum escaped, descended through the tube to the uterus, and was washed off by the menstrual blood." There is no further observation made in this paper from which it can be inferred that Mr. Cruickshank supposed all the phenomena of menstruation to depend on this state of the ovaria. Even as early as 1672, it appears Kirkringius believed that ova were sometimes discharged from the ovaria during the monthly periods; for he says, "*Aliquando foeminæ deiciunt hæc ova, imprimis tempore menstruorum.*" I have not had time to examine the work of Kirkringius, to ascertain whether he states this from an actual examination of the ovaria of women who died during menstruation, or if he adopted the opinion on purely hypothetical grounds, as Dr. Power did, and stated in his *Essay on the Periodical Discharge of the Human Female*, published in 1832.

MICROSCOPIC RESEARCHES IN ANATOMY.*

By R. D. GRAINGER,
Lecturer on Anatomy and Physiology at
St. Thomas's Hospital.

GENTLEMEN,—In accordance with the wishes of my colleagues, I have undertaken to give a brief description of the results which have recently been obtained in the science of anatomy by microscopic research. In the presence of several of the most accurate observers of the day, it might seem to be superfluous to point to the various departments of anatomy and physiology, animal and vegetable, which have been enriched by the contributions of English and Continental microscopists. It has, however, been con-

sidered, that as many of the gentlemen who have favoured us with their presence this evening, and especially those unconnected with the profession, may not be so familiar with the progress of minute observation, a reference to some of the more important discoveries which have by this means been made will not be altogether devoid of interest or utility. It must be apparent to those who have noticed, even in the most cursory manner, the rapid progress of microscopic research, that it will be impossible, on the present occasion, to enter into any detailed account of the isolated and various steps by which the existing knowledge on this subject has been attained. It must rather be my object to present to your notice a sketch of some of the leading facts which have been established by the labours of so many observers, and to point to a few of the more important inferences which the accumulated information we now possess seems to warrant.

Notwithstanding the great and important additions for which we are indebted to the microscope, it has been, and still is, too much the custom to regard this instrument as more calculated to amuse the curious than to instruct the studious; as more fitted to amaze the ignorant than to enlighten the learned.

Many of those, again, who admit the importance of determining by microscopic investigation the structure of organized bodies, assert that the conflicting opinions of observers imply defects in the mode of investigation, which, until they have been more successfully rectified than has heretofore been effected, justify a doubt as to the accuracy of all such inquiries. But an unprejudiced consideration of what has been accomplished by the microscope will, I feel satisfied, convince you, that although these inquiries are, like all the higher departments of human knowledge, beset with difficulties, they have led to an infinitely more satisfactory acquaintance with the essential characters of organized bodies, and the laws of formation, than was formerly possessed. The most conclusive answer which can be given to all such objections is, that if it be admitted that the aim of the anatomist is to discover the true structure of the human body, he must either avail himself of the use of this instrument, which affords the only means of rendering the internal composition of the several organs apparent to the senses, or rest satisfied to abandon, as beyond his power of demonstration, those very parts of the animal frame which are of the deepest interest to the physiologist and practitioner of medicine. Let us suppose, for instance, that the student traces, by the most careful dissection, the arteries, the veins, and tubes of the kidney, so far as they are visible to the naked eye, he will yet have discovered nothing

* We feel it right to state, that as the meeting included a considerable number of non-professional persons, this paper is necessarily restricted to general allusions, minute details appearing to Mr. Grainger unfitted for a mixed audience.—ED. GAZ.

of the complex machinery by which the secretion of urine is accomplished; and so, in fact, we might adduce every organ of the economy—the bones, muscles, and nerves, none of which can be displayed in their internal and essential parts to the unaided senses.

In proceeding to the more immediate object of this address, I would, in the first place, solicit your attention to some of those microscopic researches by which vegetable anatomy and physiology have been enriched. By selecting some of the more simple or cellular plants, where the typical structure is displayed unobscured by the addition of parts which, in the higher classes, renders the task of investigation so much more difficult, the botanist is enabled, with the assistance of the microscope, to demonstrate that tendency to the spiral disposition of the component parts, which so strongly pervades the vegetable kingdom. If, for example, we examine the different species of *confervæ*, it will be seen that the organic corpuscles are deposited in spirals.

A process evidently of the same kind was noticed by Schleiden, and has since been pointed out by Mr. E. Quekett, in the development of the vascular tissue of the higher plants. The latter observer has ascertained that the membranous tube which precedes the vascular tissue becomes charged with innumerable granules, which, after a short time, begin to adhere to the inner surface of the tube, assuming a spiral direction or form, and thus lay the foundation, as it were, for the vascular tissue. Again, if we watch the circulation of the *chara*, which, as a microscopic object, almost rivals in interest the circulation of the blood, something of the same kind is noticeable; that is to say, the little globules which indicate the currents going on in each cell of this plant, follow in the larger cells a definite spiral direction, so that while the globules describe curved currents, there are intervals, called by Dutrochet lines of repose, where no motion takes place. In these instances we have an opportunity of perceiving, in its simplest but most evident manifestation, that spiral form which is so eminently displayed in the whole vegetable kingdom.

And here I would remark, that one of the most important principles established by modern research is, that the anatomist, in determining the fundamental character of any organ, must seek for it in the lower forms of organic beings, where the typical structure is displayed in all its simplicity.

Another important addition to vegetable anatomy was the discovery, by Schultz, of the vessels by which the circulation of the elaborated sap, or latex, is accomplished. Previous to these researches nothing could be more unsatisfactory than our knowledge

respecting the channel by which that fluid which is to the plant what the arterial blood is to the animal, was carried to the organs which it is designed to nourish. The existence and actions of these vital vessels, as they were called by Schultz, have been almost universally admitted; there are, however, some careful microscopic observers who have not been able to satisfy themselves that a true circulation does, in reality, go on in the vessels we are describing. One gentleman possessing a very superior instrument, has repeatedly sought for the currents described, but so long as his observation was confined to the living plant in an un mutilated condition, no motion could be seen; but on making an incision, movements, which were attributed to the escape of the fluids, were observed. Without dwelling further on this point, I would only remark, what is familiar to many who are present, that motions are occasionally seen in fluids which have been mistaken for vital phenomena, although they, in reality, depend on physical causes, such as those seen in the red particles when a drop of blood is placed in the field of the microscope, or in the capillary vessels of the frog's foot when severed from the body.

I have now to allude to a series of investigations which have thrown a new and unexpected light on some of the most important laws which regulate the growth or formation of organized structures. I refer to the anatomy and physiology of cells. Although so much has been written upon this subject, a brief notice of the discoveries of Schleiden and Schwann may, perhaps, be permitted on this occasion. The first great truth which these investigations have revealed is, that although nature displays infinite variety in the secondary formations of animals and vegetables, yet that in the primary development of the several organs, one form alone, that of a nucleated cell, is observed. The mode of origin of this primordial cell appears to be as follows: the minute granules existing in the primitive plastic, but as yet unformed substance, aggregate together, and so form a small and usually disc-shaped body, which, being the rudiment or origin of the future cell, was called by Schleiden the *cytoblast* or cell-germ, though the term of nucleus, first given to this body by our distinguished countryman, Dr. Robert Brown, is still very generally retained. According to Schleiden, it is doubtful if the cytoblast is in reality the true germ of the cell; for he remarks, that in the cytoblast itself a minute sharply-defined object, presenting the appearance of a thick ring, or thick-walled hollow globule, is observed, which, forming even earlier than the nucleus, is called the *nucleolus*. From the surface of the cytoblast there rises subsequently a thin transparent vesicle; and this

it is which constitutes the walls of the cell. The celebrated German anatomist, Schwann, has demonstrated that the same identical phenomena which thus occur in the vegetable are also exhibited in the animal kingdom: and thus we learn, that whether a corpuscle of blood, a fibre of muscle, a filament of nerve, or a vessel, is destined to be formed, the foundation of each is a cell containing a nucleus, which, undergoing a series of transformations, may be ultimately converted first into a tube and then into a fibre.

This is a brief account of one of the most brilliant discoveries which, perhaps, has ever been made in connexion with the science of organization. The great principles it establishes respecting the formation of animal and vegetable tissues have been universally adopted, although some modifications, and those not unimportant ones, have been introduced by other observers into the theory as originally announced by Schleiden and Schwann. Those physiologists supposed that the nucleus or cytoblast, having performed what they conceived to be its specific office—the formation, namely, of the cell—was cast off as useless, and absorbed. Further inquiries, both in Germany and England, have shown, however, that the nucleus is a much more important organ than was originally imagined. Thus Rosenthal contends that the nuclei serve to the reproduction of the organic tissues, by becoming elongated into fibres; and Reichert, although he condemns this theory as hypothetical, conceives that Rosenthal's inquiries have shown that the nucleus does not disappear in the manner stated by Schwann. It is, however, in this country especially, that the importance of the cytoblast has been shown by Dr. Martin Barry. This distinguished observer contends, that instead of being removed after having formed the parent cell, the nucleus becomes the source of new cells; and as it is capable of dividing or multiplying itself, and of thus giving origin to objects endowed with the same properties as itself, the nucleus possesses in this kind of vegetative growth an almost illimitable power of increase. Without entering into the merits of this question, I may be allowed to point out, that although the power possessed by the primary cells, and by the tubes proceeding from them, of absorbing new matter and depositing this in their interior, was known to Schleiden and Schwann, as, for instance, in the formation of the spiral vessel of the plant, and of the muscular fibre in the animal; yet to Dr. Barry belongs the great merit of fixing the attention of physiologists on one of the most important points connected with the history of cells, the independent power, namely, in virtue of which they may increase almost *ad infinitum*. It is this endowment which is more particularly interesting to the physiologist, and to the

pathologist, as it is calculated to explain many of the phenomena connected with nutrition and secretion, as well as the growth of carcinomatous and other tumors.

This reference to the formation of the nucleated cell naturally leads me to speak of the ovum; for, strange as it may appear to some of my auditors, the new being or embryo, like all its individual parts, springs from a cell, or, more correctly, from its nucleus, called the germinal vesicle, or, from its discoverer, the vesicle of Purkinje. The limits of this paper are quite insufficient to allow me even to glance at those minute and extended researches, including numerous microscopic observations, by which our knowledge of embryology has been so remarkably enriched. I will merely call your attention to those admirable investigations of Dr. Barry, which have established, among so many other valuable results, the fact that by a process precisely the same as that described as taking place in the nucleus of the cell, the minute object discovered by Wagner, and called the germinal spot, gives origin to incipient cells, which fill the whole of the interior of the germinal vesicles. Ultimately two of these cells enlarging constitute the true germ, and then each giving origin to two other cells, the number becomes 4, 8, and so on, increasing in the ratio of geometrical progression.

The contributions to the minute structures of the various tissues are so varied, that the science of general anatomy has, within a comparatively short period, assumed a new and more important aspect; there is indeed no class of organs which has not been most carefully investigated. So extended have been these researches, that to notice them would require me to speak of every texture of the animal frame, and would thus lead to details altogether incompatible with the limits of this address.

By the judicious employment of the microscope, aided by minute injection and comparative anatomy, the characteristic corpuscles of bone, the peculiar tubuli of the teeth—and here I would especially point to the researches of Professor Owen on the dental organs of existing and extinct animals—the general structure of glands, the epithelium and cilia of mucous membrane, the ultimate fibrilla of muscle, the fibre of nerve, and the various fluids, normal and abnormal, have either been satisfactorily investigated or greatly elucidated.

Among these extended inquiries one or two subjects only can be briefly noticed. The discovery which perhaps promises the most important results is that of Henle, respecting the existence of a new element in the nucleus and even serous membranes—the epithelium." By this term, as now understood, is meant a layer of particles, which are generally considered to be modified nucleated cells, and which are essentially of the same

nature as those of the epidermis. Their form and number vary remarkably in the different organs where they are examined; for it must be understood that these peculiar bodies, although in some situations few in number, or even altogether absent, generally extend into the most minute divisions of the serous and mucous membranes; as, for instance, into the small tubuli of the secreting glands. They have been divided by Professor Henle into the tessellated, the cylindrical, and the ciliated. More lately, however, Mr. Bowman has ascertained that those called by Henle cylindrical are, in fact, prismatic in form; and he has added a fourth class, the spheroidal. As to number, in some organs, as in parts exposed to pressure—the mouth, the pharynx, œsophagus, and vagina, for instance, and especially in the glands, where they seem to form almost the whole mass of the mucous membrane of secreting tubes—they are most abundant; whilst in other regions, as the eustachian tubes and tympanic cavities, they are more sparingly distributed.

Late observations tend to show that these bodies take an active share in the process of secretion; indeed, if the researches of Mr. Goodsir be substantiated, it will be necessary to conclude that the epithelial nucleated cells are the immediate agents of that process. Mr. Goodsir conceives that the wall of each cell is the part which performs the secreting, and that the cells when they are full give way, and so pour the fluid into the beginning of the excretory duct. This theory implies the incessant destruction of the epithelium cells, which are supposed by Mr. Goodsir to be in a constant state of development, maturity, and atrophy.

One of the most curious facts connected with the epithelium is the existence, on its free or unattached surface, of an immense number of microscopic hair-like filaments, called cilia. These minute bodies, which present, when in action under the microscope, a beautiful spectacle, and of which so excellent an account has been given by Dr. Sharpey, although most abundantly distributed, are by no means co-extensive with the epithelium. They abound in all the lower classes of animals, even on the surface of some embryos, and especially in the mucous surfaces and passages. They have been lately discovered in most unexpected situations, as on the lining membranes of the cerebral ventricles, where they were first seen by Purkinje and Valentin; and on the surface of the pericardium and peritoneum in some of the lower animals: they have been doubtfully seen in the interior of the nerves by Valentin and Remak. One of the latest discoveries of these bodies is that of Mr. Bowman, who has seen them in action within the orifice of the secreting tube of the kidney.

“The last subjects, gentlemen, to which I shall direct your attention in connexion with

the investigation of the tissues by the microscope, is that relating to the ultimate structure of the muscular fibre, and as this is a point which at the present moment commands the attention of microscopic observers, I may perhaps be permitted to dwell upon it somewhat less briefly than on the topics previously noticed.”

The allusion which I made in the former part of this paper to the spiral arrangement in the vegetable kingdom, will tend to show the great importance of that disposition in one of the grand divisions of the organic creation. There are many facts familiar to botanists which will throw light on some views presently to be noticed, respecting the presumed existence in the animal kingdom of a similar principle of arrangement. It is known, for example, that by carefully tracing the spiral tissue of the plant through the several stages of its first development, and of its subsequent transformations, it can be demonstrated that various and sometimes even apparently most anomalous forms, such as annular vessels, dotted ducts, and reticulated cells, are produced simply by modifications of the fundamental or typical spiral fibre.

Now the animal kingdom presents, as it would seem, an exactly parallel transformation, in the structure of the breathing tubes or tracheæ. In the class insecta, it is familiarly known that the tracheæ, instead of being composed as in man and the other vertebrate animals, of interrupted and imperfectly closed rings, consist of a continued spiral and round filament. It has, however, been noticed by Burmeister, that in larger tracheæ, as in those of the locusta viridissima, the thread loses its cylindrical, and assumes a flattened form; and Sprengel has further ascertained the interesting fact, that in such larger tubes the spiral becomes interrupted, and forms, as in the apparently similar case of the annular ducts of plants, perfectly closed rings. But the exquisitely beautiful structure seen in the bilobed tongues of the musca vomitoria, or common horse-fly, affords a more palpable demonstration of this transformation of a continual spiral; for you will distinctly perceive that whilst the larger tubes of this remarkable organ are formed like the ordinary tracheæ of insects, that is to say of a continuous filament, the smaller tubes proceeding from it are composed of imperfect rings, of a horse-shoe form, and presenting in their divaricated extremities a peculiar percate appearance. When to these facts we add, that in one of the herbivorous cetacea, namely the dugny or fabled mermaid, the tracheæ is composed, as in insects, of the coils of a continuous cartilage, there can remain little doubt that the interrupted and imperfect rings of the windpipe of the vertebrata generally are in reality developed on the principle of a spiral.

A celebrated microscopical observer, M. Mandl, contends that a spiral arrangement is also observed in the cutaneous appendages of animals, as in the barbs and barbules of feathers, in the scales of fishes, and in the growth of hair.

Having thus cursorily noticed that there are evidences of a spiral arrangement in the animal kingdom, I may state that Dr. Barry conceives that this disposition is more or less displayed in the various fibrous organs of the body, and consequently in the muscular fibre. Most of the microscopic observers of muscle, from Leuwenhoeck, Borelli, and Hooke, to those of the present day, have however contended that the ultimate fibre is composed of a series of particles which have been variously compared to a line of beads, pearls, &c. The corpuscular theory has been lately supported by Mr. Bowman, in the admirable paper he has given on the structure of muscle. He supposes that the primitive fasciculi, or bundles of voluntary muscles, consist of elongated polygonal masses or particles, which bodies thus compose the primitive fibrilla.

According to Dr. Barry, whose views on this subject are familiar to many present, the ultimate muscular fibre is composed of a double spiral filament, which, for the sake of illustration, might be compared to the two strands of a twisted rope, to which objects, indeed, the fibre, when seen under the microscope, often bears a striking resemblance. In examining different specimens single spirals are occasionally seen, presenting in some instances an appearance exactly like the turns of a corkscrew; but the fully formed fibrilla seems, according to the account and drawings published, to be composed of two spirals. The formation of the spiral fibre of muscle and other organs, is first developed, according to Dr. Barry, in the red particles of the blood, of which process he has given a minute account. The plates in the Philosophical Transactions represent a coil of disc-like bodies, variously disposed within the elliptical corpuscles of reptiles, and the circular particles of the mammalia. And here I may mention, that it is an important part of Dr. Barry's general theory respecting the high importance of the cytotblast of nucleated cells, that the coils just mentioned are produced by the division and multiplication of the nucleus of the red particle.

Such are the accounts of two other most recent observers of the muscular fibre. It would, of course, be presumptuous indeed to attempt to decide the question; I will therefore merely mention one or two circumstances which may throw some light on this subject. That there is a peculiar spiral connected with the muscular tissue, is now admitted by the best observers. Dr. Barry has figured in one of his plates a spiral fibre

wound around a fasciculus; and some months previous to the announcement of Dr. Barry's researches, Dr. Leeson had discovered and demonstrated to some gentlemen connected with the hospital a spiral of the same character, that is to say, is wound around a primitive fasciculus. This seems, as far as I can judge from several examinations, to correspond in position to the delicate transparent sheath of the primitive fasciculus so beautifully demonstrated by Mr. Bowman, and called by him the sarcolemma. A few evenings since I was present when Dr. Leeson showed his spiral to Mr. Bowman and Mr. Busk, when the former gentleman, with perfect candour, admitted it was a structure he had never seen before. But you will observe, gentlemen, that this part of which I am now speaking does not touch the main question—the nature namely, of the ultimate fibre; for the spiral demonstrated by Dr. Leeson surrounds the primitive *fasciculus*. At the time mentioned, however, Dr. Leeson had satisfied himself that the ultimate fibre itself consists of a spiral.

It is proper to notice, that in the year 1838, Mr. Mandl must have seen something of the same kind; for he states, though this part of his account is incorrect, that the well-known transverse striæ seen on the muscular fasciculi are merely the coils of a band of cellular tissue, *spirally* disposed around the ultimate filaments.

I had intended to have pointed out some of the applications of the microscope in the investigations connected with physiology and geology; but I find that I have already so far exceeded the limits prescribed for this address, that I have only time to briefly call your attention to a subject immediately connected with our meeting this evening—namely, minute injection. Although some of the elder anatomists, and especially Ruysch and Lieberkuhn, greatly excelled in this beautiful art, which subsequently fell in some degree into disuse, it is proper on this occasion to state that several zealous cultivators of minute anatomy have lately succeeded in displaying, with a perfection which may vie with any preceding productions, the most delicate ramifications of the blood-vessels. Through the kindness of Mr. Dalrymple, Mr. Bowman, and Mr. Quekett, of the College of Surgeons, I have had frequent opportunities of inspecting the various organs thus prepared; and I think that those gentlemen who may this evening examine the vascular preparations made by Mr. J. Quekett, will coincide in the opinion that he has attained all that the art of injection, so far as displaying the disposition of the vessels is concerned, can effect. By the demonstration of the vessels thus afforded, it has been ascertained that they observe a special arrangement for each organ: thus

there is one character for the respiratory organ; a second for the mucous surface of the stomach; a third for the small intestine; and so forth.

The combined use of the microscope and minute injection is evidently introducing a new era into the history of anatomical preparations. The existing museums, although most valuable for illustrating the more demonstrative branches of anatomy, and the coarser changes induced by disease, are, in fact, insufficient either for the elucidation of the ultimate structure of the human body, or for the detection of the essential changes induced by morbid action. A well-assorted collection of injected organs, normal and diseased, and of sections and other specimens displaying the intimate structure, all of which might be contained in a small cabinet, together with a superior achromatic microscope, would do more to convey to the student a real knowledge of the human organization, than an imposing display of magnificent rooms filled with bottles, which in every sense may be said to be hermetically sealed.

In conclusion, I feel it due both to you and to myself to state, that when I undertook to present what I feel to be a most imperfect sketch of microscopic research, in its relation to anatomy, I was entirely in ignorance of the importance this meeting would assume, from the number and scientific distinction of those who have favoured the medical officers and teachers of this hospital with their presence this evening. I feel, gentlemen, that if I had knowingly undertaken this office before such auditors, I should have been guilty of great presumption; but such, I must repeat, was not the case; and I can only express my regret that I should have thus engaged your attention, when my place would have been so much more ably occupied by that distinguished physiologist to whose admirable researches I have had so many occasions to refer, and whom I am most proud to call my colleague.

MEMOIR ON
 ABRASION OF THE DIARTHRODIAL
 CARTILAGES BY FRICTION,
 AND ON THEIR
 ATROPHY FROM OTHER CAUSES.

BY ROBERT KNOX, M.D.

(For the London Medical Gazette.)

EVER since I first taught anatomy, nearly seventeen years ago, it has been with me a constant practice to direct the attention of my students to what-

ever structural changes were found in the practical rooms, and to all the deviations from the usual and natural arrangement of parts which from time to time occurred. Now of the structural changes which were observed, one in particular forced itself early upon my notice; this was "abrasion of the encrusting cartilages of the long bones, and more especially in the knee and elbow joints." A theory (as must ever be the case) soon presented itself to enable me to group the phenomena I then observed, and to predict the occurrence of similar changes provided similar causes were present; to be brief, I arrived, after a few years' observation, at the following conclusions, or abstract propositions:—

1st, That the encrusting cartilages of the long bones, and of others, may be, and are sometimes, destroyed by any contracted state of the joint, leading to an undue pressure on the articular surfaces at some points, and an absence, or at least a diminution, in other parts, of that friction necessary for the due maintenance of the healthy structure. And

2dly, Including in some measure the first proposition, that whatever alters materially and permanently, or at least for a considerable time, the system of leverage natural to any joint, must, in the end, *rub* away, or destroy, by *wasting* or want of use, the cartilages and synovial tissue of that joint, and even the surfaces of the bones themselves, unless the injury were arrested by a timely eburation of the bone; and that this effect might happen altogether independent of inflammation, ulceration, &c.

I am quite aware that in thus putting forward a theory in this prominent way, there is a danger of my readers arriving at a conclusion prejudicial not merely to it but to the whole of the facts hereafter to be stated. This, however, would be quite an unfair conclusion. During seventeen years, at least, the theory has been held by me loosely in the hand, and ever ready to be abandoned should any fact appear subversive of it; but no such fact, although searched for anxiously, having ever appeared, I cannot well be accused of haste in submitting to the profession the following series of observations.

Finally, I call it a series of observations, because they really are so; and

seeing that they have been chiefly made in presence of large classes, merit the attention of my professional brethren, altogether independent of the theoretical chain with which I have endeavoured to link them together.

As my observations, from their very nature, exclude all idea of method, I shall proceed at once to detail the organic changes observed in each of the joints in succession in which I may have observed them, commencing with the first joint of the great toe, or, as anatomists term it, the metatarso-phalangeal articulation.

The human foot, like every other part of the body, is liable not merely to great variety in form or shape, still confined within natural bounds and a strictly human form, but also to a number of deformities congenital and acquired. I shall speak first of the natural form of the foot, and of the proportionate and strictly beautiful foot, and of the probable sources of our ideas of the beautiful in respect to the human foot. The first remarkable circumstance in regard to the human foot, whether male or female, is that in childhood (I mean before the fourth year, or thereabout) the feet are almost universally well formed, and possess that form which, should it persist in the grown-up woman, all men at once declare to be beautiful. There are, of course, exceptions, but speaking of the young foot generally, whether male or female (fig. 1), I should feel

FIG. 1.

disposed to describe it as being seem-

ingly short, compared with the stature of the child; its inner margin straight, but more generally somewhat arched inwards; the great toe either placed on the same plane with the inner margin of the foot, or somewhat arched inwards, and slightly detached from the second, leaving an obvious space between them; the second toe longer than the first; all the surfaces smooth, and as if chiselled in marble; one gentle elevation, somewhat arched, carries the back of the foot from the toes to the instep; everything is taper, soft, gently traced; neither sinews, nor veins, nor bones, are visible; the whole, in fact, is eminently beautiful, and in keeping with all those pleasing and graceful forms which render the child an object of gentle attraction even to the sternest natures of mankind. After this period, sooner or later, the form and proportions of the feet begin to alter: in the boy they soon take on a masculine form and male proportions; the tendo-achillis becomes prominent and strongly defined. The foot acquires a length in the grown man equal to a sixth of the whole height of the individual; in the full-grown woman about a seventh and a quarter, or between that and a seventh and a half; that is, woman's foot is absolutely shorter, comparing height for height, than the male foot. So that if both individuals measure 66 inches in absolute height, then the male foot will, and ought to, measure eleven inches, or a sixth of the total height: I say ought, for if less, even by half an inch, an air of effeminacy and insecurity is given to the whole figure. On the other hand, the female foot of a person 66 inches in total height will be found generally to measure somewhat less than nine inches; and if more, it gives to the whole an unpleasing masculine character, a character of strength, solidity, and firmness, unsuited and unexpected in the female form. But the changes which the human foot undergoes are not confined to proportions merely; the more remarkable regard the extrinsic shape and character of the entire foot. The female foot, when perfect, retains, and ought to retain, much of the infantile or childish form; its straight inner line, and its freedom from angular proportions; but above

all, as I have already said, its infantile character, from which the male foot deviates so widely; and this it is which preserves for the finely-formed female foot, that of the Venus for example, the title of *beautiful*, to which the finest male foot has no pretensions whatever; it is the retaining of that infantile character, associated in our minds with youth and health, grace, simplicity, and truth, loveliness, and, confiding helplessness of the person. It is proper to observe here, that the foot of the very young child or infant differs from that of the child of three, four, or six years of age; it is not so pleasingly formed, retaining something of the fœtal form (which is never pleasing), an inner line too much curved, a large toe longer and stronger in proportion than what taste reckons comely, and too widely separated from the second; the foot, like all other parts of the

body, undergoing phases or changes from, and even before, birth until its maturity and ultimate decay. In a word, the fœtal forms are unpleasing; the infantile, on the contrary, beautiful.

If we turn now to contemplate the same instrument in the adult, whether male or female, whose proportions may not be so favoured, we frequently find that a congenital deformity, or at least a tendency to deformity, soon, at least in some, begins to show itself: the deformity to which I allude is that peculiar dislocation of the great toe, or change in its direction from a straight line with the inner plane of the foot (or even arched inwards) as it once was, to that of an angle, more or less acute, with the metatarsal bone supporting it, until at last it produces a plaiting, as it is called, of the toes, the large toe passing either under or over the second (figs. 2 and 3). This plaiting leaves ex-

FIG. 2.

FIG. 3.

Front view of the deformed foot.

posed the distal, large, rounded end of the metatarsal bone, which some surgeons mistake for a tumor, and treat as such, calling it a bunion: the internal lateral ligaments give way; they spread out, in fact, become lacerated, and reduced slowly, but surely, to mere shreds; occasionally a small bursa or two forms just over these ligaments; at last, the integuments themselves ulcerate, and the bone appears, which the surgeon next attacks as an exostosis and morbid growth, the anatomist knowing all the time that the whole of this surgical view is a delusion, an inconceivable error; that the metatarsal bone is, in

fact, in its place, and that nothing whatever has happened excepting a slow but constantly-increasing change in the direction of the great toe, merely producing a plaiting of the toes, a stretching of the lateral ligaments, much uneasiness and positive pain; and, should the dislocation proceed so far as to expose the joint, much distress and real suffering. In respect to the internal condition of the joint, I may here briefly remark, that the cartilages of encrustation disappear from the surfaces of the bones, which become smooth and not unfrequently take on an ivory polish. Here, then, is one cause for the destruction of the cartilages of a joint, but seemingly not *abrasion*: these cartilages have disappeared not by too much friction exercised on a part, but rather by too little, a cause just as effectual in causing the absorption or disappearance of cartilage from the extremity of bones as the opposite: it may indeed be laid down as an axiom in regard to the diarthrodial cartilages, that they are affected, more or less, by every change of the joint, whether the change refer to an alteration of the mode of leverage, or to the mere exercise of the individual parts.

The dislocation outwards of the great toe I have just described, sometimes in one foot, sometimes in both, is one of the most common deformities met with in regard to the foot. I have never seen it in any savage race, but so far as I can judge (and in Scotland opportunities for observing the naked foot at all ages are by no means unfrequent) the deformity is quite common amongst all ranks and every age, with the exception of the very young. It seems to me to arise from a congenital predisposition; every thing I have seen, every thing I have observed, and all the dissections I have made, are, in my mind, subversive of the theory of Mr. Key, and others, who maintain that it may be traced to tight shoes, to too much standing erect, aided by age and corpulency; I repeat I have never met with a single observation confirmatory of such a theory. I have seen the deformity at ten, twelve, fifteen, in the mere stripling and girl who scarcely ever had a shoe on his or her foot; the extremely corpulent and active I have observed at the age of forty, fifty, and sixty, with feet nearly as well formed

as the Venus. I have heard of many other theories equally inadmissible with the one just mentioned in respect to the cause of this so frequent deformity, but one of the last, and certainly not the least ingenious, was one propounded to me by an old six feet high admiral; he had suffered much from this dislocation outwards of the great toe in both feet, which misfortune he was not disposed to ascribe to any original predisposition, but solely to his dancing master, and to the absurd practice of civilized well-bred nations walking with their toes turned outwards; pointing out to me, with much confidence in his theory, that the savage, who had no dancing master, never had this complaint, but had at all times a well-formed foot. How ingenious are the theories of the non-professional, but at the same time how totally destitute, like many of our medical ones, of even the slightest foundation in truth.

It has often occurred to me that this deformity of the foot is more common in the Saxon than in the Celtic race, and occurs oftenest in large, raw-boned, ill-proportioned, tall persons; nature seemingly leaving, in such persons, the extremities unfinished. I have already said that the disposition to it may, in some, be seen very early; at ten, twelve, or fifteen, increasing with years, never improving, and seemingly incurable. All contrivances I have as yet seen devised for restoring the great toe to its right direction have entirely failed. The tendon of the extensor longus, and its muscle, after a time, aid in increasing the evil, by drawing the toe still more forcibly outwards; so that, in addition to the wedge which some have proposed placing between the first and second toes, to counteract the tendency to displacement and consecutive partial dislocation (which are, in fact, the essence of the disease), this tendon would require to be divided. My bootmaker lately mentioned to me the idea of an ingenious gentleman who had, in returning overland from India, visited Egypt, and being much struck with the form of the foot of the Egyptian mummy, and particularly with the remarkable straightness of its inner line and great toe, in which no obliquity outwards could be discovered, adopted for the nonce the very pretty theory that all this was owing to the form of the Egyptian sandal; and that our crooked

feet, and plaited great toes especially, could be ascribed to nothing else but to the pointed narrow form of the European shoe! Of course it never had occurred to him that something might be due to the *race* of men to whom the feet belonged; that the Saxon and the Coptic races might, after all, not be identical; that, as they differed remarkably in physiognomy, colour, shape, intellectual and physical qualities, so they might also differ in respect to the form of the foot. These were points which perhaps had never occurred to him; so he ordered his bootmaker to make for him all boots and shoes on the model of the Egyptian sandal given him for that purpose, and taken originally from the foot of a primitive Copt. I sincerely trust that the experiment may succeed: in the meantime I must retain my doubts until he satisfies me of the identity of the races.

In thus opposing the theory of Mr. Key, in regard to the causes producing this deformity of the human foot, justice to myself compels me to state that, before doing so, I have endeavoured to obtain information in every way. Being aware that nearly all "the trade" (I mean of boot and shoe makers) entertained the same or similar views, I felt that there were two of the highest authorities opposed to me; the practical surgeon and skilful observer of great eminence, and the practical workman. But now that, in this half-shod kingdom, I have looked attentively at hundreds and hundreds of naked feet, in young and old, I feel confident in the correctness of my views. One of the very last observations, as showing the congenital nature of the deformity, or rather of the tendency which leads to it, occurred to me whilst waiting for the railway train at Cupar Angus. A girl, apparently about thirteen or fourteen years of age, stood by me: she was a light figure, by no means ill-proportioned, or in any way deformed; but on looking at the feet, which, as usual, were naked, I observed a remarkable plaiting of the great toe, with the usual bulging out of the distal end of metatarsal bone. The foot seemed a little shorter than the other, which was otherwise well enough made, but showed that deep hollow between the toe and heel so frequent in the large ill made feet of many adult males and females,

which, in her case, was more strongly marked than usual. But that which struck me most forcibly was that her mother, who stood close by her, had precisely the same deformity in the opposite foot.

Thus all I have seen during the last twenty years convinces me that the deformity in question is not caused, generally at least, by the use of tight shoes (theory of Mr. Key, and of all shoemakers), nor by the instructions of the dancing master directing us to turn our toes outwards in walking (theory of the Admiral I have referred to), nor by ill made shoes generally (theory of the gentleman who had visited Egypt); but arises mainly, if not solely, from a congenital tendency or disposition in the foot of some persons to assume this form; and that—

First, it occurs at nearly all ages after five or six.

Secondly, in males and females indiscriminately, whether heavy or light made, and whether they have worn shoes or not.

Thirdly, it may be confined to one foot, or found in both.

Fourthly, it leads to an atrophy or disappearance of the cartilages of encrustation and of the synovial membrane; and as this cannot be caused by pressure, nor inflammation, nor apparently by ulceration, it must originate in the altered form of the joint, and the non-use of the cartilages themselves.

Before returning from this digression on the form of the human foot, I shall take the liberty of adding a few remarks in respect to a point or two which, to me, seem not well understood. It is well known that a short shoe or boot, although always unpleasant, may be put up with so long as the person remains seated or laying down; but let him walk about, and then the distress becomes insupportable with a rapidity dependent on the shortness of the "chaussure." Now how is this? Anatomy explains it perfectly. The arch of the foot is not a solid osseous arch, unyielding and inelastic; but, on the contrary, possesses within itself the power of elongating itself (when the weight of the body is put on the arch) by means of the calceo-scapoid ligament. The elongation may amount to nearly half an inch. The elongation is due to the elasticity of this ligament. Now if

the shoe merely fit the foot *at rest*, it cannot fit the foot *in action*; for under the weight of the body, the arch, by means of the ligament, will lengthen about half an inch: this it is which so speedily renders the short shoe insupportable. Much, no doubt, might be done by ingenious mechanics, well acquainted with the anatomy of the foot, to remedy many of the evils attending the ill-formed foot.

I now return to the subject of the loss of the diarthrodial cartilages by abrasion or otherwise. We have seen, as regards the joint of the great toe, that the disappearance of the cartilage from off the ball and socket-joint of the great toe, in the peculiar deformity just described, could not be owing to abrasion, but rather to a change in the disposition and arrangement of the articular surfaces. By the gradual slipping of the first joint or phalanx from off the rounded end of the metatarsal bone, the cartilages of encrustation are no longer opposed to each other; their functions in a great measure cease; and being, as it were, no longer wanted, they gradually break up and disappear. I am quite aware that most British surgeons will give to the process by which this is effected the name of ulceration—ulceration without suppuration; just as we sometimes have supuration without ulceration. Destruction by abrasion, pressure, "*usure*," &c. it certainly is not: may it not merely be the atrophy which attacks most organs when their functions cease? As happens to the acetabulum itself, and its powerful encrusting cartilage, when the head of the femur, being thrown from its socket, is left unreduced, the osseous cavity, which originally contained it, its cartilage of encrustation, synovial membrane, and cotyloid ligament, all disappear.

Other joints of the foot.—It frequently happens that, on opening the joint between the scaphoid and astragalus, and that between the scaphoid and inner cuneiform bone, the cartilaginous surfaces are found abraded, and the osseous tissue rough, bare, or polished. This occurs, no doubt, mostly in elderly people; and may arise, first, either from atrophy, using the term as applied to the particular disorganization and pathological condition whose precise nature has not yet been fully made

out; or, secondly, from rheumatism; or, thirdly, from want of use. But it is not my intention to say more of these joints at present, since I have unfortunately not examined them so often with the attention required in scientific inquiry.

The *ankle-joint* has appeared to me of all others least liable to the loss of the articular cartilages from the causes I now investigate. On this point I have no experience.

The knee-joint.—During the first and second sessions of my teaching anatomy, opportunities occurred of examining, with all care, in the Practical Rooms, a few contracted knee-joints. These were more or less contracted; some quite stiff; and others might be farther flexed, but not extended. On opening these joints, it surprised me to find the uniformity with which, at certain points of the femur, patella, and tibia, the cartilages had been destroyed, and, as it were, broken up; in some parts rough, and as if unravelled; in others, traversed by lines breaking them up into small fragments; occasionally the bone laid quite bare, and even deeper indented or worn into, and even scooped out, or polished like ivory, and this eburnation extending to a greater or less depth into the texture of the bone. In the meantime there was no appearance any where of actual disease; of inflammation, or its effects; of ulceration, or of purulent fluids. Whatever had destroyed these cartilages, and altered the condition of the surrounding osseous tissues and the form of the joint, it seemed clear to me that it could not have been actual active disease of any kind; and I came to the conclusion, though very slowly and reluctantly, that, in most, if not in all such cases, the cartilages had been worn off or abraded by undue friction applied to certain portions of their surface, and atrophied, in others, from a want of the healthy and free use of the joint; and that both might be traced to an alteration in the form of the joint caused by contraction or stiffening, no matter how produced; and that, whatever share rheumatism or other complaints might have in inducing a pathological condition of the encrusting cartilages of moveable joints, leading to their ultimate destruction and disappearance, it was not necessary,

at least in certain cases, and in those I now speak of (a numerous list), to resort to any such explanation in accounting for the phenomena. Friction in excess or in defect, over use or under use, or, to express it more generally and more comprehensively, but not less truly I hope, whatever alters the system of leverage connected with a joint, will, as a mechanical result, give rise to abrasion and atrophy of the cartilages and of the bones themselves, altering the form of the latter, causing exostotic depositions of a very peculiar character and singular history, and, in short, producing phenomena of an altogether unexpected nature, but strictly independent of the processes usually called inflammation, ulceration, &c.

[To be continued.]

HINTS ON THE ACTION OF BISULPHURET OF CARBON, &c.

To the Editor of the Medical Gazette.

SIR,

IN October 1841, I gave an account, in your valuable journal, of the action of the vapour of hydrocyanic acid upon diseases of the eye. Since that period I have been engaged in investigating the action of various other bodies on the same organ, and under the same form.

One reason why I did not feel satisfied with the effects produced by the hydrocyanic acid, was, that its action, like that of all other medicines, decreased in power by continued application; thereby rendering it necessary to have occasional recourse to other medicines in order to insure a more speedy recovery. Another reason was, the reluctance of many individuals to submit the eye to the action of so potent an agent. The first medicines to which I shall refer, and which I have employed with some success, are the chlorocyanic acid and sulphuretted hyazic acid.

The plan I pursue is that of putting a drachm of one of the medicines into a bottle (containing a small piece of sponge) of about two ounce size, having a mouth precisely fitted to the eye, and with a ground glass stopper.

The action of these medicines is very different from that of the hydrocyanic

acid, in as far as they both stimulate the eye, and produce much greater warmth and irritation, with less dilatation of the pupil. Few, however, can bear the chlorocyanic acid to be applied longer to the eye than half a minute; though in a minute after its application all irritation is removed, and the eye feels perfectly at ease.

The next medicine which I have employed in the form of vapour was the chloruret of iodine. This medicine produces very little warmth or uneasiness to the eye if continued for the space of two minutes or upwards; but a sensation of irritation, accompanied with a flow of tears, takes place on its removal. It contracts the pupil; and in no case have I seen it dilate it. Its vapour rises very readily, and does not leave the yellow disagreeable colouring on the skin produced by the vapour of iodine when uncombined, which is a great drawback in the use of iodine in diseases of the eye.

The last medicine which I have employed is the bisulphuret of carbon, which is so volatile that the application of it to the eye, when the bottle is held in a warm hand, for a few seconds, is as much as can be borne, in consequence of the intense pricking heat and flow of tears which it occasions. Owing to this fact, I generally use it by causing the patient to shut the eyelid during its application, which can then be continued for a minute or two, with the same beneficial effect upon the eye, without inconvenience to the patient. It generally contracts the pupil, and very seldom dilates it. I used to employ iodine by putting it into the same bottles and immersing it in warm water, and in its state of vapour applying it to the eye, but I find it answers much better when dissolved in the bisulphuret of carbon.

It is my intention shortly to give a full account of the action of these medicines upon the various forms of disease to which the eye is subject, and also what particular disease each medicine is best calculated to remove. At the same time I will state such instances of failure as have occurred in my experience, in order that a just estimate may be formed of the value and importance of each medicine.

It may not be out of place here to state that I have employed with great

success the bisulphuret of carbon to enlarged indurated lymphatic glands. In the first instance I rubbed equal quantities of the bisulphuret of carbon and alcohol upon the parts affected, but without any effect upon the glands. But as its effects were so great when its vapour was confined to the eye, I was led to apply it in the form of vapour, and by means of glass bottles similar to those I have described. By these means I excluded the action of the medicine from the external air, and thereby prevented its speedy evaporation. When it had been applied about one minute the patient felt the part very cold, but immediately after, a gradual heat, accompanied with great prickling; the heat increasing the longer the medicine was kept in contact with the part, until it could no longer be endured. On removing the glass the part was red to an extent two or three times greater than the part enclosed. In a few days the change in the size of the glands was very great, and by its daily repetition a complete and speedy removal of the disease was effected.

I also find that its action upon diseased glands is more decided if the surface of the skin is well moistened with water previous to the application of the bottle to the part. The water, in fact, not only prevents the escape of the vapour between the glass and the skin, but assists the imbibition of the carbon—a point of the highest importance, in as much as all its action on the part depends upon the exclusion of the atmospheric air from the vapour. I may here observe that these applications occasion no injury whatever to the skin.

I have also found the bisulphuret of carbon, and the chlorocyanic acid, valuable medicines in the removal of deafness dependent upon a want of nervous energy and deficiency of wax. The mode of its application is substantially the same as that which I employ in diseases of the eye, with this difference only, that the bottle is formed with a small neck and stopper adapted to the size of the orifice of the ear, and held close to the organ until a considerable degree of warmth is produced.

The action of those medicines which contain so large a share of carbon arises from the carbon in the vapour fermenting the cuticle and coming in contact with the oxygen in the vessels,

which is conveyed through every part of the frame by inspiration and otherwise, and thereby forming carbonic acid gas, which evolves heat in the ratio of the quantity consumed by the oxygen.

The following quotations from the celebrated Liebig, in his work on Organic Chemistry, sufficiently prove the correctness of this opinion:—

“It is only in those parts of the body to which arterial blood, and with it the oxygen absorbed in respiration, is conveyed, that heat is produced. Hair, wool, or feathers, do not possess an elevated temperature.”

“This high temperature of the animal body, or, as it may be called, disengagement of heat, is uniformly, and under all circumstances, the result of the combination of a combustible substance with oxygen.”

“In whatever way carbon may combine with oxygen, the act of combination cannot take place without the disengagement of heat.”

“We can no longer doubt that gases of every kind, whether soluble or insoluble in water, possess the property of permeating animal tissues, as water penetrates unsized paper.”

Does not the action of medicines containing so large a proportion of carbon, which can be brought into contact with the whole external surface of the body, and thereby capable of being easily disengaged, suggest a method of relieving pulmonary disease likely to be attended with no ordinary success, by calling into greater activity the action of the skin, and thereby materially lightening the labour of the lungs? Are we not the more encouraged to expect such remedial influence in diseases of the lungs, from the fact of its great power in removing indurated glands, which are so common accompaniments of consumption? There can be no doubt of the usefulness of bisulphuret of carbon in skin diseases.

I have submitted these observations under the conviction that they embody principles which may be carried out, and made of great utility to mankind.

I am, sir,

Your obedient servant,

A. TURNBULL, M.D.

48, Russell Square, Oct. 20, 1842.

MR. ADDISON'S REMARKS ON
MR. T. WHARTON JONES'S OBSER-
VATIONS ON THE BLOOD.

To the Editor of the Medical Gazette.

SIR,

MR. T. WHARTON JONES has a happy method of stringing together his '*Observations**', so that while he renders it difficult for his readers to discover the sources of his facts, he is apt enough in appending the names of individuals to what he calls *inaccurate interpretations*. For instance, he says:—The colourless corpuscles contained in the liquor sanguinis which has risen to the top in inflammatory blood, have been supposed to form by their coalescence the buffy coat. This inaccurate interpretation of the matter, first given by Mr. Addison, has been assented to by Dr. Barry.†

Dr. Barry I have no doubt will give the observations all the attention they merit at his hands, and for myself I beg to refer the author for my "interpretation of the matter" to the MEDICAL GAZETTE, (15th of April, 1842,) published very nearly six months before the appearance of Mr. Jones's observations.

"After removing a thin pellicle of fibrine from the surface (of the liquor sanguinis of buffy blood) with a needle, I gently touched with the point of a finger the fluid beneath, and placed a colourless drop between two slips of glass. On submitting it to the microscope I found a great number of colourless corpuscles, some of them containing in their interior several exceedingly minute molecules and granules; others, one, two, or three larger molecules or granules. There were also floating in the fluid great numbers of loose or independent molecules, varying in size, the largest being at least eight or ten times smaller than any of the colourless corpuscles. These minute molecules or granules had the appearance of dark specks, or bright ones with a dark circle, according to their approximation to the focus of the microscope. The coagulation of the fibrine had not at this time commenced in the drop of liquor sanguinis under examination; very soon, however,

the fibrinous filaments made their appearance; which, gradually increasing in number, crossed and intersected each other at various points; the molecules, at the same time congregated together in various irregular groups; the number and intricate interlacements of the fibrinous filaments inclosing and drawing together the molecules and colourless corpuscles*.

But even in the papers particularly referred to by the author of the Observations, to make out his charge of inaccuracy, I have observed, when describing the coagulation of the liquor sanguinis of buffy blood, "As the liquor sanguinis accumulates, it grows more opaque, the colourless globules become more numerous: a film forms, and at length perfect coagulation takes place *by the thickening of the film and the firm aggregation of the globules*†."

In conclusion, I think the author of the Observations would have done well to have stated where he obtained the first idea of examining the liquor sanguinis at the surface of buffy blood before it coagulates, and of the quantity of colourless blood corpuscles which it contains—whether from his reading, or his own independent researches. It would also have been more satisfactory had he substantiated his remark, that "the existence of colourless corpuscles in the buffy coat of the blood is no new observation," by stating where he had found any description of them, in which their existence, if noticed at all, was not distinctly referred either to the process of coagulation or to some analogous formation subsequent to the withdrawal of the blood from the body.

I remain, sir,

Your obedient servant,

WILLIAM ADDISON.

Great Malvern, Oct. 27, 1842.

P.S. The forthcoming volume of the *Transactions of the Provincial Medical and Surgical Association* will not be published for some time: I shall therefore feel obliged by your inserting the following brief results of my researches on the formation of tubercles in the lungs.

The blood, at all times, contains two

* British and Foreign Medical Review, Oct. 1st, 1842, pp. 583, 600.

† P. 590, loc. supra.

* MEDICAL GAZETTE, April 15, 1842, p. 144. Mr. Jones surely does not mean to deny that the colourless corpuscles have a considerable influence in the formation of the buffy coat.

† MED. GAZ. 1840-41, vol. i., p. 690.

distinct kinds of corpuscles—the one red, the other colourless. The colourless corpuscles are highly organized vesicles or cells formed from the central portion of the red corpuscles. They combine with, or adhere to, the tissues through which the minute currents of the blood circulate, and become cells, performing different functions, and assuming different forms, in various parts of the body, in accordance with the primitive law regulating the development of the organism. Thus all kinds of epithelial cells are formed of colourless blood corpuscles, and each cell performs its own function quite independent of those by which it is surrounded.

Pus corpuscles are partially formed cells; they may be seen in all stages of development, from colourless blood corpuscles in the serum of a blister, to large granulated vesicles and well-formed epithelial cells in various cutaneous diseases.

The colourless blood corpuscles have an equally important share in forming "the results of inflammation," as they have in administering to nutrition.

When, solely in consequence of their excess, their normal development ceases, they become pus corpuscles; but when they exercise an independent activity they give rise to specific forms of disease.

All the objects composing a tubercle of the lungs originate from colourless blood corpuscles. A tubercular disease of the lung is in all respects analogous to a chronic eruption of the skin (*lepra*, *psoriasis*, and *acne*); the varieties and complications of the one are neither greater nor more numerous than those of the other.

The colourless blood and pus corpuscle of man; the inner vesicle of the red corpuscle, and the colourless corpuscle or lymph globule of the batrachia; the polygastric animalcules; the pollen grain of phrenogamous plants; and the spore of epiphyllous fungi, are all analogous in their structure to each other; they are granulated cells, which may be completely dissected by Liquor Potassæ, and precisely similar objects, in great numbers, may be turned out of them all.

TWO CASES

OF "FITS:" WITH REMARKS.

By C. J. B. ALDIS, M.D.

(For the Medical Gazette.)

CASE I.—I was requested to visit Martha B., æt. 16, Sept. 29th last, residing in Hunt-street, by her mother, who stated that her daughter was in a fit, and had been so since two o'clock in the morning, and that she had suffered from a fit some time before, for which she was bled. I went immediately from the Dispensary, between twelve and one o'clock, and found the girl in bed, apparently insensible, and closely watched by her grandmother, who said that the patient had not spoken since two o'clock, although they tried to make her sensible in every way they could think of. Pulse natural; skin warm; bowels said to be costive; catamenia regular. I called loudly to her, but received no reply; she seemed to be in a complete state of stupor. On trying to raise the eyelids, in order to examine the condition of the pupils, I found that she endeavoured to close them again. Suspecting the case to be hysterical, I told the mother to bring me a jug of cold water, and threatened to throw it over her if she did not return an answer to my questions. She had previously experienced a sensation of choking in the throat at different times. When the water was brought to me I renewed the threat, and observed the eyelids begin to move. I was about to pour the water over her head, when she sat up in the bed, without opening her eyes, or returning an answer to my questions. On repeating the threat she opened her eyes, and began to speak, to the astonishment of her anxious and wearied relatives. Aperients and antispasmodics, with cold affusion every morning, were ordered. I told her to visit me at the Dispensary on the following Monday, which she did, and is now quite recovered.

CASE II.—The following is a case of a more serious nature, which occurred Oct. 24th instant. The mother of the girl applied to me at the Dispensary to visit Sarah P. æt. 12½, residing in the Horse Ride, who, she said, had not

spoken since nine o'clock the same morning. I went immediately, between twelve and one o'clock, and found the patient in bed, in a fit. Pulse oppressed; skin cool; bowels open; urine free; head warm, lips livid, foaming at the mouth, stertorous breathing. The pupils were contracted at first, but afterwards became dilated; feet cold; arms contracted across the chest; mouth firmly closed, from rigid contraction of the muscles. Previously to her being attacked at 9 o'clock, she asked her mother for some meat, which was refused; soon after, her mother observed "a working of the fingers," and coma supervened. She had pursued her occupation of fancy trimming until Saturday evening; felt poorly on Sunday, and went to bed. Nine years previously she was attacked by measles, since which time she has been subject to occasional attacks of "asthma," according to the statement of her mother. Never had a fit before. Mustard poultices were applied to the feet, cold water to head, and blood was taken by Mr. Gayton, the apothecary to the Dispensary.

After the abstraction of blood, the muscles of the mouth relaxed sufficiently to allow me to administer an active purgative, a portion of which returned through the nostrils, and the mouth became firmly fixed. Various means were resorted to with a view to restore her, but she died in four hours afterwards.

The permission of her parents having been obtained, her body was examined the next day.

The mouth was firmly closed, and the abdominal muscles were very hard and rigid.

Head.—On opening the longitudinal sinus, much dark fluid blood escaped. On removing the dura mater, the surface of the brain was observed to be congested to the last degree. The ventricles contained no effusion whatever, and there was no trace of ruptured blood-vessels in its substance, which, however, was greatly congested.

Chest and abdomen.—Old adhesions were detected between the pleura pulmonalis and pleura costalis of the right side of the chest; the lung of the same side containing more blood than natural. The heart, left lung, and abdominal viscera, were all healthy. The alimen-

tary canal contained a small quantity of feculent matter.

REMARKS.—The foregoing cases present a remarkable contrast; the first being a case of hysteria simulating apoplexy, the second presenting an example of apoplexy from cerebral congestion, which, most probably, was connected with the morbid changes in the lungs, affording an impediment to free circulation of the blood through them. She had been affected with headache at different periods for a long time. The case of hysteria affords an example of the necessity of not having recourse to blood-letting in every case of "fits," although the popular opinion may be in favour of it. The mother of the girl in this case was dissatisfied at first that I did not bleed her daughter, but when she found that the patient was able to walk to the Dispensary on my next visit, as I said she would be able to do, her anxiety in regard to bleeding ceased.

CASE OF ASCITES.

To the Editor of the Medical Gazette.

SIR,

THE following case of "ascites" presents several points of interest, which, I think, may entitle it to a place in your valuable periodical. In the first place, it would seem to have arisen suddenly, after a severe attack of hepatitis attended with peritonitis, and, from the patient's own account, her body became very large in the course of a few hours. This appears to have taken place on the remission of the pain she had previously laboured under.

Secondly, the large quantity of purgative, diuretic, and diaphoretic remedies employed, produced no diminution in the size of the abdomen: and although the bowels were freely relieved every day, still the secretions were of an unhealthy and highly offensive character.

Thirdly, this appeared a case where the operation of acupuncture might be tried with a fair chance of success, there being no apparent sign of organic disease. The great pain which was produced after each operation, with no visible diminution of the patient's size, induced me to persist no further in the

attempt to produce absorption by this means. It must be borne in mind, that this failed at a time when all the secretions were advancing towards a healthy state, and the secreting organs in a state of activity from the remedies then employed.

Fourthly, the perfect success which followed the operation of "paracentesis" after so large a quantity of fluid had been voided, and which must be attributed to the rational treatment she had persisted in some time before, and persevered in for some time after, the operation.

Nothing is of so much importance, in every surgical operation, as that of preparing the system of the patient for the shock, and to produce such a change as to prevent the recurrence of the morbid action which previously existed in the body. Indeed, this is not a solitary case in which the utmost success has crowned the efforts of my treatment in cases of malignant disease, which were considered hopeless, and probably would have proved so, but for the rational treatment of improving all the functions of the body, and removing, as far as possible, the remote causes of the disease. At a future period I may communicate some cases which will show the importance of this proposition.—I am, sir,

Yours respectfully,

WILLIAM ROBBS,
M.R.C.S.L.

Grantham, Oct. 30th, 1842.

A. J., ætat. 24, was taken ill, about nineteen months back, with palpitation of the heart, urgent pain of the right side attended with sickness, and large quantities of bilious matter were voided. This occurred while she lived in service, which she did in the capacity of a cook. The pain in the side continued about two months, with occasional swelling and œdema of the feet and ankles. On the disappearance of the pain in the side, the abdomen began to enlarge, which was attended with severe pain in its lower part. This continued for some little time, when, on the abatement of the pain, the belly rapidly increased to its present magnitude. She was under medical treatment; the abdomen was blistered, and she took medicines. The patient is of short stature, spare habit, and, when well, very active. At this time (July 15th, 1842) the countenance

presents a healthy appearance, is clear and natural. The bowels are regular; the urine is scanty, but voided without pain; the pulse beats 80 in the minute; the tongue is rather white, but quite moist. The appetite is good, and there exists no inordinate thirst. No inconvenience is experienced in the horizontal position. The systole and diastole of the heart natural, but feeble. The abdomen is of large size, the swelling uniform, the fluid apparently occupying the whole cavity of the peritoneum. Fluctuation is very distinct over every part. On a careful examination no organ presents any enlargement. The circumference of the abdomen measures thirty-six inches over the umbilicus.

℞ Pulv. Digit. gr. iss.; Hydr. Chloridi, gr. j.; Camphor, gr. iij.; Extr. Hyoscyami, gr. v. Misce, fiatque pilulæ, ij. 6ta quaque hora, sumendæ.

℞ Extr. Elaterii, gr. i.; Magnesiæ Sulph. fʒij.; Tinct. Sennæ. Syr. Simp. aa fʒj; Spt. Æth. Nitr. ℥xl. Misce fiatque haustus omni mane sumendus.

18th.—The elaterium made her very sick, but it purged the bowels freely: the motions were large in quantity, dark coloured, and very unnatural in smell. A very small quantity of high-coloured urine has been voided, which, on standing, deposits a large quantity of pink sediment. It is not coagulable on the application of heat. It is of acid quality, changing the litmus paper red. In other respects the same.—Pergat.

24th.—The elaterium produces such severe sickness and syncope, that she refuses to persevere with it. The circumference of the abdomen, for the first few days, appeared to diminish; but at this time it measures the same.

Repetantur pilulæ ut antea.

℞ Pulv. Potassæ Bitart. ʒij.; Pulv. Jalapæ, ʒj. Misce fiatque pulvis 4ta quaque hora sumendus.

August 7th.—The circumference of the abdomen very little less. The urine is nearly clear, and large in quantity. The bowels are freely acted on, but the motions continue to have a dark unhealthy appearance.

I determined this morning, as the secretions were approaching to a healthy state, to try the effects of acupuncture: I consequently made four punctures into the cavity of

the abdomen, with the needles, two about four inches and a half from the umbilicus, in a line with the superior spinous process of the ilia, and one an inch above, and the other an inch below, the umbilicus in the linea alba. A small quantity of dark yellow serum escaped after each puncture.—Pergat.

11th.—She complained of pain over the whole surface of the abdomen after the operation, which lasted for three days. The bowels continue freely acted on, and the motions are large in quantity and of a dark clay colour; the urine is clear, and natural in quantity. Her size and appearance much the same.

Repetantur acupuncturationes duodecim abdomini.

R Gum. Cambogiæ, P. Scillæ, aa gr. ij.; Hydr. Chloridi, Pulv. Digitalis, aa gr. iss.; Extr. Conii, gr. iij. Misce fiantque pilulæ duæ alterna quaque nocte sumendæ.

R Potassæ Nitratis et Bitartratis, Pulv. Gum. Acaciæ, aa ʒij.; Sacchari Albi. ʒiij. Misce accuratè divideque in chartas xij. quaram sumat unam tertia quaque hora.

15th.—She experienced much pain and uneasiness from the last operation, which has scarcely ceased. This has not been attended with any diminution in her size. The secretions have improved, and fresh bile may be observed mixed with the feculent matter. I am of opinion it is advisable to persist with the remedies till the secretions become quite in a healthy state, and then to resort to the operation of paracentesis abdominis.—Pergat.

22d.—The patient is in good spirits, and her countenance looks healthy. All the secretions have assumed a natural character; tongue clean and moist; pulse 76. I now performed the operation of tapping in the usual way, when twenty-one pints of dark yellow serum were drawn off. She bore the operation well, and nothing remarkable occurred.

Continuantur remedia.

23d.—No unfavourable symptoms have taken place; the tongue continues clean; the pulse regular, about 80 in the minute. Three pints of urine have been voided within the last twenty-four hours. The bowels have been freely acted on, but the motions

are of a darker colour, and larger in quantity. On pressure over the right hypochondriac and hypogastric regions, pain is experienced, but not of a violent character. I cannot discover the liver or any other organ enlarged.

From this time she continued her remedies, at intervals, for six weeks, when she was discharged, quite well in health, with not the least appearance of any return of the disease.

MEDICAL GAZETTE.

Friday, November 4, 1842.

“Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.”

CICERO.

MEDICAL EMIGRATION.

No man, it has been said, lives by the treatment of fevers and inflammations, or of dislocations and fractures alone. This is nearly, if not quite true: in a highly civilized community medical men seldom make fortunes by the treatment of acute diseases exclusively—perhaps in a civilized metropolis, never.

In proportion as medical education is abundant, medical skill is expected; and although the want of it is resented and punished as a misdemeanor, the possession of it is comparatively but lightly regarded. Would a man make a fortune by practising what every candidate for examination is expected to know, he must either travel into countries where such science is rare, or must persuade the public at home that he has far more of such knowledge, or a better way of applying it, than his fellows.

In this country medical science has long been diligently cultivated, and our art has been applied on recognised principles to the production of valuable results; but a long peace, a measure of free trade, and other blessings, have produced much abundance,—and much discontent. There is grumbling in physic as in farming. Patients and the

people cry out for cheap physic and cheap bread, while the doctor exclaims with the farmer, that his skill and exertion do not enable him to pay his rent, or to live as he ought; still less to enjoy the dignity of an income tax. The acquirement of wealth and honour, then, should not be the main inducements to enter our profession: assuredly they are not the general results. An increased and increasing recognition of the principles of frugality, in a luxurious age, and the rejection of the doctrine that capital is well laid out in dashing equipages and shewy houses, prove that in these days an honourable competence is all that can reasonably be looked for.

Large capitalists and skilful cultivators, many or few, are but exceptions to this rule; and although to hold up the improved rents of the Sutherland estate, or the well-earned preserves of an esteemed Norfolk baronet, may be very proper at agricultural meetings, medical dinners, and introductory lectures, yet these are not exactly average specimens of the probable results of good farming or skilful obstetrics.

But a competence; the

“clear,

For life, (blank) hundred pounds a year;”

what is to be done for a competence—in these over-tilled fields—in this overstocked profession? One of three things—perhaps more, that we wot not of,—but these three *are* done. Some emigrate; some—in all variety of type, from large posters to small pica—assure the public that not to consult them is suicide; and the rest sit cheerfully down to do their duty honestly, ever increasing their knowledge, and making the best of their opportunities to get forward.

To the second class of aspirants we have nothing to say at present. A jocose weekly contemporary describes their habits so well, and, in his letters to his son, gives so much sound counsel suited

to their views and feelings, that we may safely leave them to the gentle guidance of his *lignum vitæ ferula*, and the ample introduction which his pages can give them to that public with whom he is so deservedly a favourite.

Some, we have said, emigrate. But here the farmer and the doctor, partners in discontent, must separate, and go different ways. Righteous men, who cannot live together, and will not quarrel, have always done so. The farmer goes generally where there is much land and few men, the doctor where there are many men and few physicians. The disastrous effects that have followed the neglect of this rule prove that it is a law of nature. Medical men have gone to Canada, Australia, and similar places, where people have not time to be ill; if ill, have not time to send for the doctor; and if stricken down by wounds or deadly sickness, have no fee, or at least no *portable* fee, to offer him:—a hay-stack, a standing crop, an eligible site with water privilege, or a small flock of sheep, might be his honorarium, after a journey compared with which the longest ride in the largest union would be but a breathing canter for a spare horse. When the settler makes war with the forest, medicine may be his occasional and most useful ally, but not his well-paid mercenary.

But an old doublet makes a new jerkin, and he who has failed at home to keep a practice, may become a good keeper of sheep. It will be found that all who have got rich in Australia and other thinly peopled countries, and nearly all who have succeeded, have either relinquished the practice of physic, or have joined to it more lucrative pursuits.

That emigration may produce its best effects, not only should the best places be selected, but the fittest persons to resort to them. And for guidance in

this matter we may again observe certain differences which appear on comparing what occurs in highly civilized communities, where the division of labour is carried to the utmost extent, with what occurs in a more simple state of society.

In the metropolis a man in large practice has little opportunity for political or even municipal avocations; and what leisure he may have, it is rather his interest to conceal than to display. He therefore passes that leisure in the pursuit of collateral sciences, or in the privacy of his own house; or if he goes much into society, it is into that of his medical brethren. Now though this tends to make, and does succeed in making, professional society *very professional*, yet it has the good effect of favouring a high cultivation of the art; for although men whose minds are of a low order are content to talk for a whole evening about the comparative value of their neighbour practices, or the probable successor to the next hospital vacancy, yet those of a higher stamp can hardly meet without gaining and giving information of a scientific kind.

The chief advantage from the frequent meeting of medical men amongst themselves, is the affording a legitimate time and place for professional conversation; and it will be found, by the way, that those who habitually absent themselves, or are excluded from such meetings, are the most apt to acquire a habit of talking professionally—of lecturing, in fact, in mixed society. This offence against good taste arises either from vanity or quackery. There is vanity in talking of what we know better than our hearers, and there is quackery in parading our knowledge before those who may become customers for the article exhibited. Among professional equals, rivals, and superiors, the temptations to

both these frailties are lessened, and the offence itself is less tolerated.

It is a symptom of a profession being too full for the actual work it has to do, when its members, instead of seeking exemption from public duties, are frequent candidates for public offices. It may fairly be questioned whether many of our brethren do not consider their exclusion from serving as grand jurymen rather as a hardship than a privilege, yet the terms of exemption evidently prove it to have been formerly considered a burden. In the Papal States, all the high government offices, and most others, are filled by ecclesiastics. In Great Britain, the majority are occupied by lawyers. Now the church at Rome, and the bar in England, are the professions which have the greatest number of unemployed members; and whatever national or political reasons there may be for choosing from these classes, it is quite clear that the principal cause which leads any class of men to avoid seeking public appointments is their finding full employment and sufficient remuneration in their own special calling.

Another cause for medical men not rising often to political eminence, is what may be termed professional specific gravity. The pressure of one kind of intellectual exertion condenses, as it were, the faculties, gives concentration to the thoughts, and weight to the character. This last cause operates not only on classes, but even more strongly on individuals. On the other hand, the intelligent doctor, “*qui se connaît en tout, même un peu en médecine*,” will be excelled in solidity, but will greatly excel in buoyancy.

Now in a new country, and one thinly peopled, where it is not pretended that the minds of professional men are directed exclusively to their art, leisure and intelligence often lead

medical men to seek for, and to fill with dignity, the highest places in the social system. Many of the first men in the United States of America have studied and practised medicine.

It follows, then, that the man of general intelligence is the best for a new country, as being most able to adapt himself to new circumstances, and most likely to appropriate and to sustain a prominent part in the social drama in which he is acting.

Those of more exclusively scientific acquirements must, if they remain at home, bide their time, and take the chance of their labours being appreciated. To those who cannot afford to wait, probably the best prospects for medical emigrants are offered in the populous but ignorant countries of the East. The proverb, 'Parmi les aveugles un borgne est roi,' expresses a fact which we should hope would tempt few of our readers; but there are great things to be seen, to be learnt, and to be done, on the South and East of the Mediterranean—as we hope to show on a future occasion.

COLLEGE OF SURGEONS.

AN announcement appeared in one of our contemporaries last week, and has since been copied into several of the daily papers, to the effect that the Council of the College of Surgeons had come to the resolution of admitting to examination all who presented themselves before January, even although they might not have complied with the regulations of the College as to their professional education. This is a mistake; no new regulations have either been made, or are contemplated. But, as heretofore, all are admitted to examination who have complied with the regulations which were in force at the time they pursued their professional education. If, for example, any

one applying for his diploma could show that he completed his studies five years ago, but had been prevented by accidental circumstances from coming to the College sooner, he would only be required to have complied with the regulations which then existed, and not with those which have since been made.

SALE OF POISONS.

MOST of our readers are aware that the sale of poisons upon the continent is limited by severe laws, the infraction of which is visited by heavy penalties. The punishment does not hang over the head of the offenders, like the sword of Damocles, terrific but inactive; for the law is neither obsolete nor obsolescent. Let us cite a few instances of its activity in France. A woman, wishing to commit suicide, bought an acid preparation of Prussian blue. She swallowed it, but her life was saved by judicious treatment. Still, the grocer who sold it to her was fined 3000 francs (£120.) for vending it without observing the forms decreed by the law of the 21 Germinal of the year XI. (*Journal de Chimie Médicale*, March 1842.)

In the same number of the same journal we find an account of another grocer condemned to an equal penalty. He had sold *eau seconde* by mistake instead of vinegar; and a lady having eaten some salad made with it was attacked with general weakness and indisposition, which had not gone off when the trial took place.

It seems that two different preparations are known by the name of *eau seconde*; the one being a solution of potash, the other a mixture of equal parts of commercial nitric acid and water. In the opinion of the editor of the *Journal de Chimie Médicale* neither of these preparations could have been used in this instance, as either one would have given the salad so marked a flavour that it would have been uneatable; while it was deposed that the salad in question was flat and tasteless.

In a third instance, a *pharmacien* was fined 3000 francs for having sold a nursery-maid some poisonous pills with which she committed suicide. (*Journ. de Chim. Méd.* Sept. 1842.)

In Belgium the law is similar, though the fines are smaller. Apothecaries are bound to keep poisons, such as white or black arsenic, corrosive sublimate, and opium, safely locked up in a place of which

they alone have the key. Poisons are not to be given to any one without an order written and signed by a doctor of medicine, surgeon, accoucheur, apothecary, or some well-known person, and with directions to be employed for some known purpose, under a penalty of 100 florins, (£8. 6s. 8d.) to be doubled on each repetition of the offence. These directions must be preserved, under a penalty of 50 florins.

If an apothecary discovers, or suspects, that there is an error in a prescription, he is bound to go to the physician or surgeon who wrote it in order to learn his intentions, but is not to correct the suspected error of his own accord.

Even the stringent laws of France, however, are not sufficiently rigorous for M. Cormenin, who proposes to forbid arsenic to be sold by retail under any circumstances. Medicine, he says, has derived no real advantage from it; and householders, instead of using arsenic, might stop up the holes in their walls more carefully. Nor would he allow it to be sold wholesale, excepting to licensed and well-known manufacturers, furnished with a certificate from the mayor, and a written declaration.

From this extreme of rigour, come we now to the other extreme of laxity, and let us see how matters are managed at home.

About a month ago, a medical practitioner in London, being in attendance on a lady suffering from inflammation of the bowels, ordered her to take a table-spoonful of potash water, diluted with an equal quantity of milk. The servant went to a neighbouring chymist, and procured an ounce of *liquor potassæ*, which was labelled "potash-water." Half an ounce of this was administered to the patient, who immediately exclaimed, "You have poisoned me; I am all on fire!" and appeared to be in great pain. The lady survived a fortnight, and, on a *post-mortem* examination, extensive disease of the stomach was found, as well as hæmorrhage in the brain. How much of this may have been caused by the potash it is utterly impossible to determine; but it is probable that the caustic accelerated her death, in spite of the immediate use of the stomach-pump and appropriate antidotes.

Another most important question remains, How should the blame incurred be divided among the parties concerned?

The practitioner, it seems, told the patient's sister that the remedy was an effervescing beverage like soda water, and offered to write down the name, but she said that this was unnecessary. The servant, when questioned by the druggist, did not know for what purpose the remedy was required. The druggist, again, appears to have given the medicine without any other warning but his question. The friends of the patient

were not struck by the want of effervescence in the solution. On the whole this catastrophe seems to have been one of those tragic incidents, where a single word would have been safety, but where that word was wanting.—*Annals of Chymistry and Practical Pharmacy*, No. 4.

LIQUOR OF HYDRIODATE OF ARSENIC AND MERCURY.

MR. DONOVAN has published farther observations on this remedy, containing a great mass of evidence in its favour. We can only make room for what follows:—

The dose has been variously represented. Dr. Kirby is disinclined to doses exceeding 20 minims, and this quantity he conceives sufficient to secure its curative effects. Sir Henry Marsh, in the case of a boy, twelve years old, began with 15 minims twice a day, and gradually pushed it to half a drachm; and at length the patient got half an ounce in divided doses during twenty-four hours, which only produced "very mild insalivation." In venereal eruptions, Mr. Cusack found one or two scruples three times a day sufficient; but even when larger doses were given, he did not observe any unpleasant consequences. Dr. Irvine's patient took ʒss. three times a day, for seventy-six days, and was only twice obliged to discontinue it for two or three days, owing to headache and sickness of the stomach. Dr. Graves's patient, a woman 60 years old, took ʒss. four times a day, for two months, with only two interruptions owing to disagreement. These instances show how differently the medicine can be endured by different constitutions. It is certainly prudent to begin with Dr. Kirby's doses; but after a while, as in the case of tartar emetic, a state of tolerance is induced, and then the medicine may be gradually increased at discretion.

The smallness of the quantity of arsenic and of the other elements, that sometimes effects a cure, is striking, and affords an additional proof of the energy which they acquire by combining chemically. In one of Dr. O'Reilly's cases, three drachms of the liquor were successful, containing $\frac{3}{4}$ grain of arsenious acid, $\frac{3}{4}$ grain of peroxide of mercury, and about $2\frac{1}{2}$ grains of acidified iodine; in another, $\frac{1}{2}$ more of these elements was required. One of Dr. Ferguson's patients was cured by $2\frac{1}{2}$ grains of arsenious acid. Dr. Osbrey succeeded with about a grain of arsenious acid; Dr. Graves with $2\frac{1}{2}$ grains; and Sir Henry Marsh, in an obstinate case of tinea capitis, with $\frac{1}{4}$ grain. Cases, however, occasionally prove of a very obstinate and tedious nature; and, generally speaking, skin diseases offer lengthened resistance to curative measures: thus Dr. Irvine's pa-

tient was under treatment 76 days, and required seven ounces of the liquor, equivalent to seven grains of arsenious acid; Dr. Graves' patient, of 60 years old, required 10½ grains; Sir Henry Marsh's, a child of 12 years, required a far greater quantity; some of Dr. Kirby's patients were a year under cure; and I know a lady, who being troubled with psoriasis almost all her life, is now, after a year's treatment, only beginning to improve.

The diseases in which practitioners have hitherto found the liquor of hydriodate of arsenic and mercury to be useful, as appears by the foregoing testimonies, are the various forms of psoriasis, impetigo, porrigo, lepra, venereal eruptions, both papular and scaly, pityriasis, sycosis, epheles, lupus, sibilens, and some uterine diseases.—*Dublin Journal of Medical Science.*

EXPERIMENTS ON KIESTEINE.

By DR. KANE, of Philadelphia.

My mode of conducting the experiments was this:—The recent urine was placed in open glass cylinders, of diameters varying from an inch and a half to that of a common tumbler, and protected from dust by paper covers. These were arranged in a dry, well-ventilated room, where the temperature was uniform and moderate, and were exposed in groups to the equal action of air and light. I examined them frequently during the day; but as the changes were not rapid, I determined after a little while to note only one set of observations in the twenty-four hours. My notes were always made upon the spot. If from any cause an individual observation or a series was unsatisfactory, or inconclusive, or if it led to a different result from others, I repeated it at once with increased care; and I was always careful to observe the constitution, habits, and circumstances generally of each patient.

The examination of the first group of cases satisfied me that the urine during pregnancy assumes appearances different from those witnessed under other circumstances, and which I was therefore disposed to regard as characteristic of that state. Subsequent inquiries confirmed me in the general accuracy of this opinion, but compelled me at the same time to admit its liability to exception.

The more obvious of these appearances regard the superficial formation described by Dr. Bird, and recently investigated by Drs. M'Pheeters and Perry; but there are others which point to a series of intestine changes somewhat more obscure, though scarcely less interesting. My observations applied to both; and I regret that the limited time at

my command during the studies preliminary to graduation obliges me to select a single class as the subject of this dissertation. I take, however, that indication which seems to me best fitted for practical usefulness in diagnosis, the *pellicular change*, and which I suppose to be most properly called the *kiesteine*.

The urine, submitted to observation in the way I have described, presents but little change during the first thirty-six hours. The mucous flocculi, if they exist, gradually subside during this period, forming a whitish cloud-like deposit at the bottom, and sometimes on the sides of the glass; while more or less alteration occurs in the colour and transparency of the fluid.

The surface remains for a short time entirely unchanged; but in most cases a greater or less number of shining acicular specks, apparently crystalline, begins to be seen within the first eighteen or twenty-four hours. These are generally scattered over the surface without regularity; but in some rare cases they are so disposed as to form a translucent film of uniform thickness, which afterwards assumes the more defined characters of the pellicle. How far these crystals are essentially connected with the formation of the pellicle, I am not prepared to say. In many cases I have not succeeded in detecting their presence, even by the microscope; and, indeed, I have failed to discover any *unvarying* indications whatever of the approaching development of the *kiesteine*.

The cloud-like appearance, which is alluded to by Nauche and Eguisier, although possessed of much interest, I have not found to be a uniform premonitor of the forming pellicle; I have supposed it to be nothing more than the enæorema of the older writers, depending upon the imperfect aggregation of mucous flocculi; for I have seen it repeatedly when there was no pregnancy to account for it, and it was uniformly absent where the fluid presented perfect transparency.

The time at which the pellicle begins to form varies considerably. I have seen it well marked at the end of thirty-six hours, and have known it make its first appearance as late as the eighth day. At first it is hardly discernible. It is generally seen forming at the centre or on the sides of the glass, presenting a delicate milky or bluish-white aspect. It is, however, in some cases uniformly disposed over the surface from the commencement, and assumes the appearance of a nearly transparent film, which gradually becomes more distinct. But it has not always the continuous strongly marked character which some have ascribed to it. I have seen it begin in striated irregular lines somewhat resembling a spider's web, in rings, circles, trapeziums, and irre-

gular fibres of every shape, which gradually became obscured by the full development of the pellicle.

When it has attained this stage, which occurs generally about the fifth day, it presents a continuous scum of an opaline white or creamy appearance, with a slight tinge of yellow, which gradually becomes deeper and more decided. The uniformity of this colour, however, is generally broken by granulated spots of a clearer white, giving it a dotted or roughened aspect. The crystals of the forming stage now appear like shining points, and I have sometimes found numerous small brownish specks, sprinkled over the surface, not unlike the gratings of nutmeg. It is at this period that the pellicle may be compared "to the fatty scum of cooled broth." In this state it continues for some time, preserving all its characters unbroken. The glass, where the surface meets it, is discoloured by a white opaline ring; and a series of such rings, varying in extent from a line to the fourth of an inch, marks the descent of the surface during the progress of evaporation.

The cheesy odour, mentioned by Dr. Bird as a valuable aid in diagnosis, and as "by no means unfrequent in those specimens in which the pellicle is very thick," I have found in but seven cases. Many pellicles of great thickness were entirely without it; and in two of those presenting it, the pellicle was thin and not very well developed. Drs. M'Pheeters and Perry were unable to detect it in either of the twenty-seven cases examined by them, and I have found it unequivocally developed in at least three cases in which pregnancy did not exist.

The pellicle, if left undisturbed for some days, breaks into cracks, commencing generally from the central portions, but not always extending to the edge of the glass. These are again crossed by other fissures, and the pellicle is more or less broken up. In the meantime, the flakes, which have been forming from the commencement of disintegration, have their edges depressed into the fluid, while at the same time the general thickness of the pellicle is much diminished; and this depression or dip gradually increasing, the depending particle is detached, and sinks slowly to the bottom. Its complete disintegration, however, is but seldom seen; being anticipated by the decomposition of the fluid. The deposit is of course considerably increased by the fallen portions of the pellicle, and is found irregularly disposed over the bottom of the vessel; but as I have remarked, most abundant on the side farthest from the light.—*American Journal*.

WARM BATHING.

THE story of Æson becoming young, from the medicated bath of Medea, seems to have been intended to teach the efficacy of warm bathing in retarding the progress of old age. The words *relaxation* and *bracing*, which are generally thought expressive of the effects of warm and cold bathing, are mechanical terms properly applied to drums or strings; but are only metaphors when applied to the effects of cold or warm bathing on animal bodies. The immediate cause of old age seems to reside in the irritability of the finer vessels or parts of our system; hence these cease to act, and collapse, or become horny or bony. The warm bath is peculiarly adapted to prevent these circumstances, by its increasing our irritability, and by moistening and softening the skin, and the extremities of the finer vessels which terminate in it. To those who are past the meridian of life, and have dryskins, and begin to be emaciated, the warm bath, for half an hour twice a week, I believe to be eminently serviceable in retarding the advances of old age.—*Darwin. The Loves of the Plants: Note on Canto 1.*

PRESERVATION OF LEECHES.

A QUANTITY of pure clay is procured, to which must be added as much pure water as will make it so plastic as to be easily formed into *irregular shaped balls*, say two inches and a half in diameter. These are placed into a square deep wooden box, or, what will answer equally well, a five-gallon keg; *a cover is quite unnecessary*. The leeches are then put in, immediately on which they creep down the sides of the balls of clay, and there remain. When required for use, the balls are carefully removed, and the leeches are taken out. It will invariably be found, that leeches kept in this way will, without hesitation and at once, lay hold of any part to which they may be applied. It will be borne in mind that the balls must be renewed weekly. It is unnecessary to expatiate on the advantages of this mode of preserving leeches over others, since a single trial will be found as satisfactory as it is here represented.—*Annals of Chymistry.*

CASES OF FRACTURE.

DR. BOMHARD RITTER has published some remarkable cases of fracture in Hufeland's journal:—

The first was a case of a highly hysterical young woman who fractured the forearm by a fall from a carriage. After the fracture had been carefully put up, the patient was re-

peatedly attacked by hysterical paroxysms, during which the opposing surfaces of the fracture became displaced, and so much injury resulted, that the patient died on the third day.

The second case was of a man, upwards of sixty years old, who fell from a height upon the ground. The head of the humerus was both fractured and luxated. The luxation was reduced, and the fractured parts maintained in apposition, and rest enjoined. After six weeks the bandages were removed, and by degrees the patient recovered the use of his arm and was able to return to his work.

The third case is one of comminuted fracture of both bones of the leg, in which, by means of extension and counter extension, and careful bandaging, the fractured portions of the bones were reduced, and after some time united, so that the patient recovered the use of the limb.—*Rust's Magazine*; and *Dublin Journal of Med. Science*.

LUBANSKI ON THE URINE OF PREGNANT WOMEN.

It is seldom as acid as in other individuals, occasionally it is neutral, and sometimes alkaline, and generally light-coloured. Donne suspected that the salts of lime for the most part are diminished during pregnancy, and that a part of them is taken to supply the materials for the formation of the foetal bone; and he found in many experiments instituted for this purpose, that by the addition of thirty parts of hydro-chloride of lime to fifty parts of urine, there was a precipitate of from forty to fifty parts of salt of lime in common urine, whereas in that of pregnancy the most he ever detected was thirty, and very often not near so much. Before making the experiment, the urine to be tried must be tested, to ascertain if it be alkaline or acid, and if acid, a few drops of ammonia must be added to render it alkaline, since the precipitate from phosphate of lime is soluble in weak acids. If the experiment be made with solution of baryta, there will be in healthy urine a precipitate of from twelve to fifteen parts of salts of baryta; in the pregnant, from five to eight, after twelve hours' rest. With reference to the question of pregnancy, Donne has, out of thirty-six cases, only twice been deceived. Lubanski found it decisive in three cases of pregnancy, where manual examination and auscultation proved unavailing. He proposes the following questions for investigation:—1. At what period of pregnancy does this diminution of the salts of lime take place? 2. Is it always constant? 3. In what relation does it stand to the increase of foetal ossification? 4. At what period does it cease.—*Ann. d'Obstetrique*, &c.; and *Dub. Journ. of Med. Sc.*

THE CHANGE WHICH EXTRACT OF RHUBARB UNDERGOES IN KEEPING.

It has been observed some time ago, by M. Landerer, that old extract of rhubarb, when mouldy, acquires a strong smell of storax. This has been confirmed by M. Reinsch, in the case of fluid extract of rhubarb which had been kept for several years in an unopened bottle, the extract being covered with a film of mould. This liquid extract was submitted to distillation, and afforded a slightly turbid water, with a great number of small drops of oil. The product of the distillation has a strong smell of storax, and was neutral to test paper. Ether, after agitation with it, becomes slightly coloured yellow, and acquires the odour of storax; after the evaporation of the ether on a watch-glass, there remain only a few drops of an aromatic oil, smelling strongly of storax, but which is very volatile, so that in about an hour no trace of the smell could be discovered on the glass. This smell of storax in extract of rhubarb which has become mouldy, arises from the formation of a peculiar oil. There will probably be many more of these oils discovered, originating in the putrefaction of vegetable matter. This oil of rhubarb appears to be analogous to the oil with the smell of musk, discovered by M. Rossignon, in decayed apples, which he has named *malolite*, and which is composed of $C H N O$.—*Repertorium für die Pharmacie*; and *Pharmaceutical Journal*.

LIQUOR TARAXACI.

A VERY elegant preparation has been introduced under the above title, and which, from the strong taste it possesses of the recent root, has been much used by medical men who have confidence in the remedial power of Dandelion. The following formula has been communicated to us:—

Dandelion roots, perfectly clean, dried, and sliced, 18 ounces.

Infuse for 24 hours in a sufficient quantity of cold distilled water to cover them.

Press and set aside, that the feculæ may subside; decant and heat the clear liquor to $180^{\circ} F.$, so as to coagulate the albumen; filter the liquid whilst hot, and evaporate in a drying room, or by means of a current of warm air (a water or steam bath will not succeed so well), until the product shall weigh 14 ounces. To this must be added 4 ounces of rectified spirit. Should the roots not have been perfectly cleansed, the product must be digested with pure animal charcoal. If properly prepared, *Liquor*

Taraxaci resembles in colour pale Sherry, and possesses the acrid taste of the fresh root in an eminent degree. The dose is from one to three fluid drachms. — *Annals of Chymistry*.

TRANSFUSION OF THE BLOOD OF A GOAT INTO THE VEINS OF A MAN.

By DR. BLIEDING.

A MAN 38 years of age was seized with an hæmoptysis, which continued so long, and so violent, that the only means of saving his life appeared to be by supplying the loss of blood by transfusion. On the fifth day after the attack a canula was introduced into the median vein of his left arm; a syringe, previously heated, was filled with blood drawn from the jugular vein of a goat, and about five ounces were injected into the vein of the man. Immediately he complained of a feeling of oppression; but this soon afterwards went off. An attack of phlebitis came on next day, but was subdued in eight days, by means of cold applications alone. His strength from this day returned, and at the end of three months he was able to resume his usual occupation. It is remarked, as the interesting point of this case, that it proves that the injection of the blood of one animal into the veins of another is not necessarily fatal. — *Journal de Pharmacie*; and *Edin. Med. and Surg. Journal*.

ADDENBROOKE'S HOSPITAL, CAMBRIDGE.

At a general meeting of the Governors, held on Monday last, October 31, Mr. Charles Lestourgeon, Mr. John Hammond, and Mr. George Murray Humphry, were elected Surgeons to this hospital, in the room of Messrs. Lestourgeon, Sen., Okes, and Abbott, who have lately resigned.

MEDICAL COMPETITION.

ON the death of Mr. Malcolm, which took place last week, there appeared in the *Times* of next morning letters from not less than ten medical men, offering themselves as candidates for the vacant office of Surgeon to the Surrey County Goal.

ROYAL COLLEGE OF SURGEONS.

LIST OF GENTLEMEN ADMITTED MEMBERS.

Friday, October 28, 1842.

W. M. Dalgliesh. — M. M. Bull. — J. Rogers. — J. H. Forster. — H. C. Wildash. — E. Moore. — J. Wade. — R. B. Penny. — W. Dalton. — J. H. Steele. — R. Barnes. — T. S. Lee.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED
CERTIFICATES.

Friday, October 14, 1842.

T. Peat. — J. Moore. — H. D. Scholfield. — J. Rhodes. — W. Boyd. — C. Telfair. — J. Vickerman. — J. I. Acheson. — J. M. Best.

A TABLE OF MORTALITY FOR THE METROPOLIS,

Shewing the number of deaths from all causes registered in the week ending
Saturday, October 22, 1842.

LECTURES

ON THE

THEORY AND PRACTICE OF MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE V.

On the Anatomy and Physiology of the Gravid Uterus.

AT the time of conception the whole uterine system is in a state of great nervous excitement and vascular congestion: the corpora fimbriata turn round to the ovaria, and the ovum, before or after escaping from the Graafian vesicle, and entering the canal of the fallopian tube to be conveyed to the uterus, is fecundated by the seminal fluid, which penetrates to the surface of the ovarium. Soon after this the corpus luteum begins to be formed in the ovarium, from which the fecundated ovum has been discharged. No opportunity has occurred of determining with certainty, in the human subject, when the ovum leaves the Graafian vesicle after conception, how many days it requires to pass along the fallopian tube, and what changes take place in the uterus before the ovum enters its cavity. Our knowledge of these subjects consists of inferences from observations made upon the lower animals soon after impregnation.

In fifty hours post coitum in the rabbit, De Graaf found the vesicles in the ovaria empty; but the ovum was not visible in the tube till seventy-two hours had elapsed. Haller saw the Graafian vesicle in the sheep ruptured two hours after; but he could not perceive the embryo in the uterus before the seventeenth day. Mr. Cruikshank opened a rabbit two hours after, and then the calyces or Graafian vesicles, which contained the

ova, projected much above the surfaces of the ovaria; and some of the ruptured orifices were just visible: but in many of these calyces there was not the least vestige of an orifice. In another rabbit, opened the third day after impregnation, the appearances were the same, only the corpora lutea were larger, and no vestige of an ovum could be discovered, either in the tubes or horns of the uterus. Another rabbit was opened the fifth day after impregnation: the appearances were similar, only the corpora lutea were increased in bulk, and no ovum could be detected any where. A fourth female rabbit was opened on the eighth day: the ova were in the cavity of the uterus, and "projected through its substance" about the size of a large garden pea; the embryo was not visible, but it became so by dropping distilled vinegar over the spot where it was known to be. Another rabbit was opened on the ninth day, and the embryo was seen within its amnion. Some corpora lutea had cavities, others none, nor the least appearance of orifice. The corpora lutea kept increasing with the foetus, were of a sand-red colour, and very vascular. Another rabbit was opened at six days and a half: there were ova in the horns of the uterus, which had just begun to fix, but did not adhere by vessels: they were much enlarged, compared with the sixth, and the side next the uterus had a round rough spot in it: the chorion and amnion were almost in contact with one another: they were easily turned out of the uterus, which embraced them every where loosely but at the bottom: corpora lutea were now increased exceedingly in vascularity, and nourished by a large vessel running across the tubes. Mr. Cruikshank examined another rabbit at three days and a half: the ovaria had the appearance as if the ova had not yet gone out; however, many of them were found in the uterus, and many in the tubes: I got, he says, about six; others were lost, from the great difficulty in slitting up the fallopian tubes without bruising the

ova: there were eight or nine corpora lutea in one ovarium, and two only in the other: on the side of the two, only one ovum was found, but twice as large as those on the other side. In another experiment at two days and a half, the ovaria were impregnated; but there were no ova in the tubes, nor orifices in the corpora lutea. Mr. Cruikshanks inferred, from these and other observations on the doe, which were made with the greatest possible care, and of which an account is published in the *Philosophical Transactions*, 1797, that the ovum enters the uterus on the fourth day.

The same volume of the *Philosophical Transactions* contains the following account of some experiments made by Dr. Haighton also upon the rabbit soon after impregnation:—"Having procured several virgin rabbits in a fit state for impregnation, I admitted one of them to the male. Twelve hours after it was killed, and on examining the ovaries several of the vesicles evidently projected: they had lost their transparency, and were become opaque and red: when punctured, a fluid of the same colour escaped. I made sections through some of them; but at this early period, the corpora lutea, which are formed by a thickening of the parietes of the vesicles, were not very evident; I therefore determined to examine them in a more advanced state. Another rabbit being admitted to the male, I examined it twenty-four hours afterwards. The colour of the fluid contained in the vesicles was similar to that of the last experiment. The vesicles projected more evidently, and their thickened parietes, manifesting the commencement of corpora lutea, were become more apparent. I inspected the ovaries of another rabbit forty-eight hours post coitum. At this period the vesicles seemed to be in the very act of bursting; and a semi-transparent substance, of a mucus-like consistence, was beginning to protrude from some of them; others, indeed, were less advanced. The fimbriated extremities of the fallopian tubes were preparing to receive their contents, as appeared by their having quitted their usual position, and embraced the ovaries in such a degree that only a small portion could be seen until the tubes were taken away. Sections being made into the thickened vesicles, the formation of corpora lutea appeared to have made further advances. From the appearance of an incipient rupture of the vesicles in this experiment, it was but reasonable to expect that their contents would soon have escaped; but as my views were directed to the formation of a corpus luteum, I deferred the next examination to a more distant time. In two days and twelve hours after coition, I examined the ovaries of another rabbit. The foetal rudiments had escaped; but the cavities of the ovarian ves-

cles had suffered but little diminution. Bristles were easily introduced by the ruptured orifices. In this experiment the advances towards the formation of a perfect corpus luteum were such as the period of examination would naturally lead us to expect. The contents of the vesicles having escaped, it was but reasonable now to look forward to a speedy obliteration of the cavity. I therefore examined these parts under similar circumstances on the third, fourth, and fifth day. In the last experiment there was but little vestige of cavity, consequently the corpora lutea might be considered as perfectly formed." I quote these observations of Dr. Haighton because they have been often referred to, and not because any satisfactory conclusions can be drawn from them.

Kuhlemann found Graafian vesicles of the sheep to have burst at the end of the first day; and Hausmann found them nearly all burst in seventeen hours.

Dr. M. Barry examined rabbits four, six, eight, and eight and a half hours post coitum, and he found the ova still within the ovaria, and apparently not very near the time of their expulsion. A rabbit was examined at eleven hours; when the ova were found to have made their exit from that organ; and at ten hours with the same result. Another was killed at nine hours; the ova were still within the ovaria, and their Graafian vesicles presented no decided indication of an approaching rupture: he says (in the *Phil. Trans.* for 1839), "I tried 9½ hours, when the ova were again found within the ovaria; while in another instance at nine hours they had escaped. At length, after nearly a score of rabbits had been devoted to anatomical inspection, for the single object of determining the condition in which the ovum leaves the ovary, the parts were found in a state precisely what I had so much desired to meet with; one of these animals, at ten hours, yielding me two ova that had left the ovary and advanced an inch into the tube, and two others that were still in the ovary, but beyond all doubt on the point of following them."

During the three first months of pregnancy, the human ovarium, from which the fecundated ovum has been discharged, and which contains the corpus luteum, is readily distinguished from the other ovarium by its greater size and weight, and by a prominence on some part of its surface above the adjacent peritoneum. On the point of this projection, there is always a small irregular depression or cavity where the peritoneum appears to have been torn. Numerous arteries and veins ramify around this prominence, and give it a red colour like blood. On cutting open the ovarium in the long direction, the corpus luteum comes into view, which is of an oblong form, rather

more than half an inch in length, and less than a quarter of an inch in thickness; it presents an entirely different appearance from the stroma of the ovary, and is wholly different from it in structure, and from every glandular part of the body. The corpus luteum is nothing but the empty Graafian vesicle which contained the ovum, surrounded by a layer of yellow granular substance which is formed subsequently to impregnation. The two coats of the Graafian vesicle are always enclosed within the yellow substance; and they can be separated from one another, and their existence as two distinct organized membranes as clearly demonstrated, as the amnion and the chorion. The innermost of these coats is smooth, and the outer layer rough and filamentous, and processes are sent out from this exterior layer which penetrate the yellow substance to a considerable depth, and in some parts go quite through it to the stroma of the ovary. The cavity of the Graafian vesicle varies in size in different corpora lutea; in some it is entirely empty, in others it is filled with a serous fluid, but I have in no instance seen the cavity of the true corpus luteum filled with blood or "lymph matter" of any description. The layer of yellow substance, which has, in the second month of pregnancy, a deep orange colour, is usually from a line to a line and a half in thickness, and when examined with a magnifier, appears to consist entirely of yellow granules contained in the cellular membrane, interposed between the outer surface of the Graafian vesicle and the stroma of the ovary. Blood-vessels pass through the yellow substance from the stroma of the ovary to the coats of the Graafian vesicle. In some specimens of corpora lutea, there is an irregular and unusually large quantity of yellow substance formed on one side of the Graafian vesicle, which causes it to press inward upon the cavity. The outer surface of the yellow matter is in immediate contact with the stroma of the ovary, which is sometimes slightly condensed, so as to produce the appearance of a capsule around it. This condensed portion of the stroma of the ovary is often thicker than both coats of the Graafian vesicle, and the mouths of divided vessels are distinctly perceptible in it, as in other parts of the substance of the ovary. In some specimens there is no condensation of the substance of the ovary around and in contact with the yellow matter, nor the slightest appearance of any capsule enclosing it.

As gestation advances, the corpus luteum gradually diminishes in size, the deep yellow colour fades, the coats of the Graafian vesicle contract, and in the fifth month its cavity is almost obliterated. In the seventh and remaining months of pregnancy, there

is no cavity within the corpus luteum; the coats of the Graafian vesicle have contracted still further, and assumed a white membranous appearance, with small processes passing outward through the yellow matter, somewhat like radii from the centre of a circle. A still further diminution takes place in its size, and in three or four months after delivery the yellow matter and coats of the Graafian vesicle have been entirely removed by absorption from the ovary; and except a small depression on the surface where the prominence had at first existed, and a slight condensation of the substance of the ovary beneath, there is no vestige left of the corpus luteum. As these changes continue to go on in the Graafian vesicle, and around it, subsequently to the discharge of the ovum and its other contents, they probably contribute, or are the means which nature employs, to fill up the cavity thus suddenly formed in the ovarium, and to promote the contraction and absorption of the coats of the vesicle after the performance of its proper function, and the necessity for its removal, has occurred—a process analogous to the conversion of the umbilical vessels, for example, into cellular tissue after their functions have ceased.

A corpus luteum is invariably formed in the ovarium after conception, and two or three where there are twins or triplets. Not unfrequently two corpora lutea are present in the ovaria where there is only one ovum within the uterus. I found a perfect corpus luteum in the ovary of a woman who died from inflammation of the uterus soon after the expulsion of a mass of serous cysts, or hydatids, as they are called, from its cavity. Corpora lutea, such as have now been described, may be regarded as furnishing the most unequivocal proof of impregnation, but it is necessary to know, that conception may have taken place, and that the corpus luteum may be so small and so imperfectly formed as to be in a great degree destitute of its genuine and distinctive characters.

In the ovaria of women who have never been pregnant, yellow oval-shaped bodies are sometimes found which it is difficult to distinguish from true corpora lutea. These false corpora lutea most frequently result from blood effused into the cavities of the Graafian vesicles, as Dr. Montgomery has observed, which assumes a fawn hue as the colouring matter disappears by absorption and undergoes various changes similar to those which are observed to take place in coagula of blood formed in the cavities of veins from inflammation of the coats, or mechanical obstruction. After a longer or shorter period, the blood is entirely removed, and the coats of the vesicle contract, and often assume a brown, yellow, or black colour. In these

false corpora lutea the yellow substance is contained within, or attached to, the inner surface of the Graafian vesicle, and does not surround it, as is the case in true corpora lutea. In advanced life a thickening of the layers of the Graafian vesicle not unfrequently gives rise to appearances resembling corpora lutea. These, and all other corpora lutea, are generally, but not invariably, found more or less deeply imbedded in the substance of the ovarium, or if they are near the surface, they are most frequently not in actual contact with the peritoneum, but have a small portion of stroma intervening. If there is a cicatrix over these, it has a more irregular form than in the small circular depression on the apex of the true corpus luteum.

In a specimen of false corpus luteum which I examined with Mr. Wharton Jones, not long since, there was yellow matter deposited in the coats of the Graafian vesicle, which were spongy and thickened. The cavity of the vesicle was distended with coagulated blood. The inner layer had a peculiar wrinkled appearance, similar to what Von Baer has represented in his figure of the true corpus luteum, and we could not help suspecting that this puckering had led him to entertain the erroneous views, respecting the true corpus luteum, which he has promulgated in his work *De Ovi Mammalium et Hominis Generi*; in fact, that he mistook a false for a true corpus luteum.

There are upon the table five specimens of the true corpus luteum in the second and third months of pregnancy; and two in the fourth, and several others in the seventh and subsequent months of gestation, and one three months after delivery. This specimen, [exhibiting it,] was obtained from the body of a woman, who died on the 11th July, 1838, in St. George's Hospital, in the second month of pregnancy. The appearance of the ovum made this certain. The left ovarium contained the corpus luteum, which was larger than the other, and had a considerable prominence on its convex edge, around which were seen ramifying a number of minute arteries and veins. There was a small circular depression at the point of this prominence, but a bristle could not be made to pass through it into the central part of the ovary. On cutting open the ovarium the corpus luteum presented itself of an oval shape, and of a deep or rather light orange colour, with the Graafian vesicle enclosed within it, the coats being thickened and contracted. The cavity was empty. With little difficulty, while the parts were under alcohol, I succeeded in separating one half of the vesicle into two distinct layers, which are clearly seen in the preparation; a bristle being interposed between them. If you look carefully through a magnifier at these two layers of the Graafian vesicle, and at the

drawing, I think you will be satisfied, as many anatomists who have done so have been, that this internal membrane is evidently something very different from "a layer of coagulable lymph," as has been asserted. The outer surface of the Graafian vesicle is so loosely attached by cellular membrane to the yellow matter, that it can easily be separated from it. Around the outer surface of the yellow matter, and completely investing it, there is a white layer varying in thickness, the outer part of which loses itself in the substance of the ovarium, of which it appears to form a part, and to be similar in structure. The inner portion of this white layer, which appears to be condensed stroma, is separable on the one hand from the yellow matter, and on the other from the substance of the ovarium, so as to give the appearance of a distinct membrane, considerably exceeding in thickness both layers of the Graafian vesicle. This preparation first induced me to believe that both layers of the Graafian vesicle are enclosed within the yellow matter of the corpus luteum.

FIG. 1.

The correctness of this view was soon placed beyond all doubt, by this specimen [exhibiting it] of corpus luteum in the second month of pregnancy. It is here most evident that there is no capsule interposed between the yellow matter and the stroma of the ovary, and that both layers of the Graafian vesicle are enclosed within the yellow matter. On one side the coats have been separated, and a bristle placed between them, that they may be more clearly seen. The separation of the coats was effected with greater difficulty than in the other specimen; and the fact rendered still more obvious that the inner coat was not a layer of coagulable lymph. Sir Astley Cooper and Mr. Wharton Jones examined this preparation, in the most careful manner, and satisfied themselves that the account I have given of the corpus luteum is

correct, and to Mr. Jones I am indebted for this accurate drawing, which has been engraved in the 22d volume of the *Medico-Chirurgical Transactions*.

FIG. 2.

On the 25th Feb. 1840, I examined, with Mr. Wharton Jones, this corpus luteum [exhibiting it], which was removed from the body of a woman who died in the 4th month of her pregnancy. The yellow matter was here likewise in immediate contact with the stroma of the ovary, and had no capsule around it; within the yellow matter, and loosely adhering to it, was seen the Graafian vesicle, like a small white cyst. When this cyst was cut open under water, there was seen a very small cavity in the centre. There were two perfectly distinct coats, which formed the walls of this cyst, and these two layers were separated by a less dense structure, apparently cellular membrane of a bluish or milky appearance.

In this preparation [exhibiting it] of the corpus luteum in the seventh month, there is no cavity in the centre, and the coats of the Graafian vesicle present a thin membranous appearance with bands running into the yellow matter, the colour of which is very pale. The whole corpus luteum is much reduced in size. (See Fig. 3.)

In this preparation [exhibiting it] there is nothing unusual visible in the ovary except a slight depression on the surface, and a white line running into the stroma to the extent of about a quarter of an inch. This is the ovary of a woman who died three months after delivery, and which contained the corpus luteum.

The corpora lutea of the sheep, in these four specimens, [exhibiting them] present a very different appearance from human corpora lutea. They resemble soft, oblong,

FIG. 3.

vascular tumors, imbedded in the substance of the ovaria, and projecting, like small nipples, considerably beyond the surface of the organs. There is a smooth circular depression on the projecting point of each of them, but there is not the slightest appearance of a cavity in their centre, nor is there a distinct capsule like the outer layer of the Graafian vesicle surrounding them.

The corpus luteum of the cow, about the fourth month of pregnancy, forms a large mass in the ovary about an inch in diameter, and projects still more than in the sheep. In this specimen [exhibiting it], the blood-vessels of which have been injected, there is also a smooth circular depression on the most projecting part, but there is no cavity in the centre, as in the human corpus luteum. Between the stroma of the ovary and the corpus luteum there is only a thin layer of cellular membrane interposed. The absence of the central cyst and cavity in these corpora lutea renders it extremely probable that the Graafian vesicles had been entirely extruded from the ovaria after impregnation; and the same circumstance must have occurred in some of the ovaria in the rabbit, described by Mr. Cruikshank. On examining the corpora lutea of the sheep, cow, and mare, you will have great difficulty, I think, in believing that they can possibly be formed by a development either of the inner or outer layer of the Graafian vesicles, or by a separation of their two coats and the sudden formation between them of the peculiar substance constituting the corpus luteum. It seems contrary to all the sound principles of physiology to suppose that the coats of the Graafian vesicle which are about to be removed from the ovary as extraneous

matters, should suddenly lose their natural appearance, and grow into these great vascular and granular masses.

The human corpus luteum was first described by De Graaf in 1672. The account he has given of it is so good that I cannot forbear quoting it.

"Quæ verò secundum naturam aliquando tantum in mulierum testibus inveniuntur; sunt globuli, qui glandularum conglomeratarum adinstar ex multis particulis à centro ad circumferentiam recto quasi ductu tendentibus conflantur, et propriâ membranâ obvolvuntur. Hos globulos non omni tempore in foemellarum testiculis existere dicimus: quia post coitum tantum in illis deteguntur, unus aut plures, prout animal ex illo congressu unum aut plures fœtus in lucem edet. Neque illi adhuc in omnibus aut ejusdem generis animalibus semper eodem modo sese habent, in vaccis enim flavum, in ovibus rubrum, in aliis cineritium colorem sortiuntur: præterea aliquot post coitum diebus tenuiori substantia præditi sunt, et in sui medio limpidum liquorem membranâ inclusum continent, quo unâ cum membrana foras propulso, exigua solum in iis capacitas superat, quæ sensim ita aboletur ut postremis gestationis mensibus ex solidâ tantum substantiâ conflare videantur: enixojam imminuuntur, ac tandem evanescent." It was afterwards similarly described by Røderer, Dr. W. Hunter, by Haller, and others. Professor Baer is of opinion that the corpus luteum is formed in all animals by a thickening of the inner membrane of the Graafian vesicle. Dr. Montgomery believes the corpus luteum to be surrounded externally by the outer membrane of the Graafian vesicle, whilst its cavity is lined by the inner membrane of this vesicle. Dr. Paterson has adopted the same opinion. The first two figures accompanying his paper in the *Edin. Med. and Surgical Journal* [exhibiting them], evidently represent false corpora lutea. They have not one of the characters of the true corpus luteum. Fig. 2 shows nothing but a clot of blood within the Graafian vesicle. There was no ovum detected in the uterus, although minutely and carefully examined: "indeed," he states, "although this person had conceived, there can be little doubt, from the puckered and contracted appearance of the fimbriated extremities of the fallopian tube, which could hardly admit of a small probe to enter, that no ovum could have passed into them." "This woman had been married eight years, and had had no family," which, with other circumstances, makes it certain that she had never been pregnant; and that a true corpus luteum could not exist in the ovary. These figures, Dr. Paterson says, "are intended to represent the external and internal appearance of a *corpus luteum*, a very short time after the rupture of the Graa-

fian vesicle. "An interesting specimen of a corpus luteum," observes Dr. P., a very little older "than the above described one, occurred to Dr. John Reid, lately, in the Royal Infirmary: the patient, a young female about 18 or 19 years of age, came into the house labouring under peritonitis, of which she died on the third day after her admission. The left ovary presented a corpus luteum, with its edge about two or three lines thick, beautifully plicated, and of an intensely yellow colour; the centre was filled with a coagulum of blood. I had not an opportunity of examining this specimen till after its immersion in spirits: the plicated margin was then quite distinct, but the central coagulum was gone. The uterus of this girl was also slightly enlarged, and contained a soft decidual membrane." As Dr. P. does not state that an ovum was detected, I am entitled to presume that it was not, and that the proof of conception having taken place was wanting. The presence of a membrane in the uterus, like the decidua, has been met with when there was no pregnancy, or has been expelled from the uterus in dysmenorrhœa. In a court of law the evidence of pregnancy here would have been considered wholly insufficient. No figure is given of this corpus luteum, and no inference can be drawn from the description of it.

The third figure represents the appearance presented by an ovarium removed from the body of a woman who died of chronic disease of the brain. Here also no ovum could be detected by Dr. P. in the uterus, upon minute microscopic examination, to determine that pregnancy had actually taken place; although he infers "that impregnation had occurred from a fortnight to three weeks before death." If you examine this figure, you will see that there is no capsule interposed between the yellow matter and stroma of the ovary; and the same is the case with the fourth figure, [exhibiting it] which represents a true corpus luteum in the second month of pregnancy. Dr. Allan Thomson says, in his description of the corpus luteum, that a cavity existed in the interior of this corpus luteum similar to what is seen in all true corpora lutea; but Dr. Paterson says this statement "is erroneous, as its centre was filled up with a reddish grey-coloured fibrinous mass." In fig. 5 the Graafian vesicle is seen distinctly within the yellow matter; and this, you see, is in immediate contact with the stroma of the ovary; although Dr. Paterson says, in his description of it, that "external to the yellow body was also a firm membrane."

These are all the observations on the true corpus luteum contained in Dr. Paterson's paper, and I leave you to judge whether they are sufficiently numerous to warrant him in stating that he had "had many oppor-

tunities of observing that the proper substance of the corpus luteum was covered by two membranes." This inference, indeed, does not appear to have been drawn from an examination of human corpora lutea, but from those of the cow. "Any one may satisfy himself of this," he says, "by a very simple experiment. Let him procure the ovary of a cow containing the corpus luteum. In this animal the parts are so large as to be easily distinguished. An incision is to be carefully made through the peritoneum and proper tunic of the ovary; and then, turning these edges aside, no difficulty will be experienced in turning out the corpus luteum from the ovary. On examining it we find that it is still covered with its cellular envelope. Upon gently cutting through this, and reflecting it, we find that the orange-coloured corpus luteum is still covered by a proper tunic; and when this is cut through, and elevated with the forceps, the naked corpus luteum comes immediately into view. Now what else can this second tunic be but the external membrane of the Graafian vesicle?" Look once more carefully at this corpus luteum of the cow [exhibiting it], with all its blood-vessels injected, and see whether it agrees with the description I have now read.

Before taking leave of this subject, the importance of which you will hereafter be more aware of than now, I ought to state that Dr. Martin Barry thinks the corpus luteum is formed by a development of the outer layer of the Graafian vesicle. Prof. Owen also thinks that the yellow substance is formed in this way, and that the inner layer is compressed by the outer, and that the cavity in the centre of the corpus luteum is anomalous.

LUMLEIAN LECTURES,

*Delivered at the Royal College of Physicians
in London, 1842,*

By THOMAS MAYO, M.D. F.R.S.
Physician to the Marylebone Infirmary.

LECTURE I.

On Nervous Apoplexy and Palsy.

Case from Morgagni, requiring for its explanation an hypothesis distinct from that of compression: such hypothesis first distinctly afforded by Dr. Kirkland. Apoplexia gravior viewed by him as a nervous affection, but incurable; his hypothesis useful in milder forms of nervous apoplexy: illustrative cases. Nervous palsy, compared with that from compression: illustrative cases. Grounds for considering this subject; its importance, and the prior neglect of it.

In a former course of Lumleian lectures, I

professed to adopt, and I carried out, as far as time allowed, a method of inquiry, which the following considerations suggested, and which, if you will permit the recapitulation, they will explain.

I noticed, at the commencement of those lectures, the richness of our medical literature, both in collections of cases and in monographs. And I adverted to the kind of use to which these cases or series of cases are usually turned, with some expression of doubt whether these correspond to the magnitude and extent of the materials.

The most legitimate use, I observed, to which such treasures are subservient, is the formation through their means of general principles. The most common are, that of furnishing arguments in support of some preconceived opinion. They are in the latter way often converted into advocates for error, instead of being tests of truth.

But I then called the attention of my hearers to a third use to which these records are applicable; namely, that of carefully examining and commenting upon cases, without any preconceived hypothesis in the procedure. The aspect, I observed, which a given case assumes, when we look at it with a view to gain whatever information it may bestow, and that in which it may present itself when we would support or may be compelled to abandon our own preconceptions by its means, are very different; and though the latter relation may be more favourable to discovery, the former, as it is more unbiassed, is more favourable to truth.

The principles of inquiry then adopted I shall again endeavour to carry into effect, and I shall again seek materials in the works of John Baptist Morgagni.

As in my former lectures I have considered on this principle some important diseases of the thorax and abdomen, I shall on the present occasion furnish myself out of his stores with a topic among cerebral diseases. I shall speak of apoplexy, holding myself responsible not for an exhaustive inquiry into this subject, but for keeping within its admitted limits, though I may not attempt to define them, and using distinctions, not as final and satisfactory, but as tending towards ultimate truth.

"A certain citizen of Bologna," (the case occurs in the 4th letter of the 1st book on diseases of the head), "who was about 70 years old, of a pallid countenance, had a difficulty of hearing, and was sometimes liable to vertigo and faintness. He had also a tremor, which was attributed to his having handled quicksilver for many years past. In other respects he was healthy and robust; so that he frequently indulged himself in sensual pleasures. Having the day before indulged in this kind of excitement, being very sprightly both in body and mind, he walked

abroad with a friend; but scarce had he parted from his friend one hour and a half, when he was found dead in the road. We observed, that the upper limbs were very rigid and contracted, and that even then there was a little heat about the right side, though 24 hours had elapsed since his death. The abdomen we did not open, but diligently inspected all the viscera and vessels of the thorax, and found them all sound. In the head we observed the mouth to be drawn to the right side, and on the same side we observed also a large blackness; but whether from the blow in falling we could not discover. The blood in general was found very fluid, but there was no appearance in the skull or about it which corresponded with this external blackness. The brain was rather soft, flaccid, and discoloured, and in it some serum was found, but more on removing the dura mater than in the ventricles. The plexus choroides was beset with turgid vesicles, as it often is; and in the left vertebral artery, very near its anastomosis with the other artery, were thin small plates, some resembling a tendinous, some a cartilaginous, and some a bony consistence."

The case here given is one of those by which Morgagni illustrates his serous form of apoplexy. He deals cautiously enough with this distinction, but leans to the hypothesis that the serous effusion is in some cases the essential symptom. "If," says he, "you set aside the last circumstance mentioned, and some other things, which, though they may be in some measure accessory to the cause of an apoplexy, are nevertheless found in many who are not apoplectic, then that little quantity of serum will remain, to the acrimony of which you may refer the cause of the convulsion of the brain."

This case, however, and many others, which Morgagni adduces to the same effect, will easily bear another interpretation, and even illustrate another very important head of cerebral disease; which, particularly since the publication of Dr. Kirkland's commentary on apoplectic and paralytic affections in 1792, has obtained the name of nervous apoplexy.

In the Infirmary of St. Marylebone, I witnessed the examination of a patient who had died under cancer of the womb. She sunk, apparently, from pain and irritation occasioned by the local complaint; and it was observed that not the smallest appearance of cerebral disturbance had presented itself in her symptoms. In the ventricles of this female four ounces of fluid were collected; much more had escaped. It was noticed, indeed, that the ventricles were in a remarkable degree patent, and, as it were, dilated. Now, when in the very highest degree of cerebral disturbance a very small quantity of fluid is found, as in the case extracted from Mor-

gagni, and when, under circumstances in which the brain has during life undergone no such disturbance, a large quantity of fluid is found, the causation of apoplexy by effusion becomes surely very problematical.

The case quoted from Morgagni expresses that the subject of it was affected by a tremor, attributed to his having handled mercury. He was subject to occasional faintings, and had in other ways subjected himself, being advanced in years, to nervous irritation. This suggests a view of the subject on which it may be profitable to dwell.

The view to which I advert is indirectly sanctioned by all those writers who represent nervous affection as a cause, and not merely and always an effect, of diseased actions; but the first person who gave it a shew of practical efficiency in cerebral disease was Dr. Kirkland, of Ashby.

In his pamphlet on "Apoplectic Affections and diseases connected with the subject," there is a two-fold division of apoplexy. The apoplexy of former writers—a disease presumed to ensue upon vascular action producing sanguineous or serous effusion—constitutes the second head of the disease, to which Dr. Kirkland gives the generic title apoplexy.

Out of the cases to which other writers had given the name apoplexy in the generic sense, he detaches those in which vascular plethora, congestion, or extravasation, had not occasioned the attack. These constitute his *first* head of apoplexy, as he considers them the more violent. They are all marked by suddenness of invasion, but have also shades of difference, some being more vehement, others milder. The entire head or species he denominates nervous. The more violent form he describes in the following terms:—"We wish to be understood to speak of a disorder in which the patient falls down suddenly as if he were thunderstruck, into a profound sleep, with snoring and sonorous respiration: he is destitute of motion, except in the thorax and heart; insensible; and has a hard, full, disordered pulse, accompanied with a relaxed or dilated countenance, and a flushing of the face."

Suddenness of invasion, and the absence of evidence of prior arterial excitement or effusion, are the diagnostics on which Dr. Kirkland principally relies as identifying his nervous apoplexy. It may co-exist with, or be promptly followed by, sanguineous or serous effusion; but these are not its causes; and he supports his opinion, as to the independent nature of this apoplexy in relation to co-existing effusions, by arguments drawn from the phenomena of concussion, appealing to a case in which the blow and some of its most apoplectic consequences must probably have preceded by some time the effusion of blood. But, finally, he ex-

presses an opinion that this form of apoplexy (that is, the graver variety of it) is from the first a mortal affection. I shall presently point out how far the principles by which Dr. Kirkland limits our practice in this attack are likely to give it that very termination which he thus predicts.

For the immediate practical value, then, of Dr. Kirkland's views, as contemplated by the author, we must look to the milder modification of this disease, which is termed by him still, in contradistinction to the apoplexy of pressure, the second species of nervous apoplexy. His description is defective. The following case will best explain his meaning, as well as suggest practical inferences.

"A gentleman, *æt.* 40, was seized, soon after dinner, with sickness and giddiness. He fell down, and a hard sleep followed; but when stirred in order to awaken him, he muttered, and sometimes moved his limbs a little. It was evident that he was delirious, but his face was neither dilated nor relaxed, as is usual with those seized with the violent nervous apoplexy. An emetic was given him by his apothecary, which operated well, but without mitigating the symptoms; for I found him, some hours afterwards, nearly as described: his pulse about 90, and full, but without the irregularity so manifest in a vehement apoplexy. Ten ounces of blood were removed and five grains of James's powder directed every five hours, till his bowels should have acted. By the time that three doses had been given, this occurred freely, and he was apparently better. A similar procedure being continued, on the third day he was able to walk down stairs, and read the papers, his pulse being reduced to 70: still a sleepiness remained. For the removal of this, 'cupping and blistering was recommended,' Dr. Kirland observes, 'in consultation by another practitioner.' The rest I give in Dr. Kirkland's exact words:—

"When the surgeon came in the afternoon, the patient desired him to go up stairs with him to get the cupping business over; but it fatigued him; and when the blister began to operate, he became convulsed and delirious. A second blister was applied to the head during my absence; and when I saw him soon after, his countenance was relaxed and dilated, and death took possession in a few hours." "Hoffman," he observes, "has informed us of instances in which irritating purges had a similar result."

This case fairly exhibits our author's bias in his practice in apoplectic cases:—the readiness to admit other causes than vascular fullness or action, and to recognize the expediency of a soothing rather than irritating procedure in their treatment, as being disorders primarily of the nervous tissue—in this sense, that compression has not obviously preceded them; and this, I may observe, is the sense

in which I must be understood to repeat the term.

Puerperal apoplexy has often occurred with very little antecedent vascular excitement. The following cases, drawn principally from this head, may illustrate the practical bearings of the above hypothesis. Four of them are cases of puerperal apoplexy; and of these four, two fall under the head of nervous apoplexy: no vascular action or congestion appears to have preceded them. In the 4th and 5th case much vascular action or congestion must have preceded the attack; and in one of them the effect of treatment adopted consists with the view taken of this distinction. One of the cases here given, the second in order, is one of nervous apoplexy occasioned by fear.

A healthy woman, aged about 30 years, near the full period of gestation, fell down suddenly: she instantly became insensible, and a stertor ensued, accompanied by a hard vibrating pulse, and violent convulsions; these returned periodically. A natural presentation of the child being ascertained, it was presumed that delivery would soon take place, and this event, as was hoped, would bring with it a mitigation of the above symptoms. It did occur in a few hours; yet the symptoms of apoplexy remained unabated. Dr. Kirkland therefore gave the patient 30 drops of laudanum. Next morning, the insensibility, stertor, and convulsions, remaining, after a clyster, which had a proper effect, 20 drops of laudanum were ordered every 10 hours till the symptoms should abate. At the end of the third day advantage had manifestly been gained over the disease. In four days recovery appeared certain: it happened accordingly.

In this case, it will have been observed, the pulse is described as hard and vibrating.

Mrs. B. about 40 years old, had an apoplectic seizure after a great exertion from fear. She had lain about 24 hours, without speech or having swallowed any liquid. She was then forcibly raised in bed, and a spoonful of a solution of aloes in wine put into her mouth. This was done every hour with broth, and wine and water intervening, till evacuations were procured; which, with other means, had good effect, and she recovered, except that a considerable hemiplegia remained, and some affection of speech. This case is given by Dr. Darwyn.

About 14 years ago, at Tunbridge Wells, I was sent for to a case nearly the counterpart of the one first narrated. The lady, aged 26 years, had suddenly fallen into a state of complete insensibility, on which stertorous breathing rapidly supervened. In this state she was first seen by me, about two hours from its commencement. She was delicate in figure and appearance; of a bilious temperament with no sanguine intermixture;

far advanced in pregnancy : her confinement, indeed, daily expected. I thought it expedient to have this lady cupped ; and I gave her some aperients and some calomel, modifying the vigour of this treatment in relation to her present state and general constitution. Not the slightest benefit, nor indeed any very obvious change, resulted from these measures. In about 30 hours she was delivered, easily, of a living child, with no relief to her symptoms ; in about 24 hours from that event she died.

Janet Allen, æt. 32, of a slender form and spare habit of body, being in good health at the time, was suddenly seized with unusually acute pain darting through the head while at the wash-tub. The pain was, however, momentary, but she complained of shivering and chilliness on going to bed. Her husband, next morning, found her in a profound sleep, breathing high. He succeeded in waking her, but she was unable to speak. Her head being raised from the pillow, she became sick, and vomited. Mr. Kellie, who reports this case to Dr. Cheyne, finds her pulse 110, full, and rather hard ; the right side completely paralytic ; a strong tendency to sleep, but a capability of being waked up. Attempting to speak, she was inarticulate. Twenty ounces of blood were removed in the morning, and sixteen in the afternoon, without any other change than that the pulse became softer, and the face less flushed. Calomel, with cathartics and a lavement, were given, from which free evacuations and urine resulted. The sequel of this case was similar to the last. The next day she was delivered of a child without any change of symptoms. As day advanced, she became more soporose, and the motion of the left arm ceased. The next morning, early, she died. She was examined. The contents of thorax and abdomen were natural ; the sinuses and external surface of the brain showed nothing abnormal ; but a coagulum of blood, weighing 11 drachms, was found in the left lateral ventricle.

The next case which I lay before you is furnished by Mr. Edwards, of Bath. Its prominent features are as follows :—A young married woman is taken in labour with her first child. After the pains have continued some hours, the membranes are ruptured ; but, through the ignorance of a female attendant, the pains are allowed to continue unassisted from Monday to the ensuing Friday morning : Mr. Edwards is then called in. He finds the os uteri nearly dilated, and one of the superior extremities presenting. With difficulty and much loss of blood from the placenta, he delivers this patient of a living child.

Meanwhile, namely, on the Thursday, first, violent pain of the head, next, dimness of sight, apoplexy, convulsions, and hemi-

plegia, had occurred ; and the latter symptoms continued unrelieved by delivery. Her pulse, when this occurred, was 130, full, and vibrating. Now the causes which led to this apoplectic attack were such as implied vascular action, and the practice adopted corresponded with this view. Twenty ounces of blood were taken from the arm, and, soon after, fifteen from the temporal arteries. The first abstraction diminished the frequency of the pulse, the second abated the convulsions. In two hours more, the pupils continuing dilated, other ten ounces of blood were taken : and this sufficed, assisted, as it was, by the action of aperients. By the eighth day, the patient was convalescent, being entirely free from cerebral symptoms.

Now if we contemplate the five cases here given, in no one of the first three have we any evidence of antecedent vascular fulness or effusion. In each of them, these vascular states, if they existed at any time, were probably consecutive to the nervous shock. And if we attempt to elicit from these cases principles of practice, with a view to preventing such consecutive congestion, and its effects, we are compelled to admit, that those two cases terminated the most favourably in which the practice had been most sedative and antispasmodic.

The two last reported cases commence, not in an overwhelming shock of the nervous system, but in pain of the head, and gradually proceed into convulsions and the apoplectic stupor ; the first of them with sickness. This sequence of symptoms places them in the class of apoplexy from compression, according to the experience of Dr. Abercromby*, which I am happy to accept, as giving value to my own ; sanguineous effusion being presumed to have occurred at the moment of "acute pain," and to have gradually increased. In the first of these two cases, that of Janet Allen, the symptoms were not observed early enough after their commencement to give depletory treatment its due efficacy. In the second case, these symptoms commenced while Mr. Edwards was in attendance on the labour. They appear to have been adequately appreciated, and to have been controlled by well-managed depletion.

Leaving for my next lecture some important modifications of the above doctrines relative to apoplexy, I proceed to consider that form of palsy which may be deemed analogous to the nervous apoplexy.

* Uniform and extensive extravasation of blood is described by Dr. Abercromby as characterising this class of cases, which begin with a violent attack of headache, and pass into apoplexy gradually. The rupture he seems to consider coincident with the first derangements of the functions of the brain.

Of the spontaneous or true palsy from a sudden loss of nervous power.

This is the expression by which Dr. Kirkland describes "a paralytic affection not brought on by compression, suppuration, or any mechanical cause." My concern with his views is entirely practical; and therefore I do not stay to ask the question why this is more a true palsy than that with which he thus contrasts it. It is the form of palsy to which he applies his therapeutical solidism, his treatment based on the hypothesis that the brain may be dealt with in relation to its nervous, and not its vascular constituents.

Now in illustrating these views, I shall take a case from a class of affections justly considered by Dr. Kirkland as analogous to the nervous palsy which forms our present subject; because I can find no other case which so well illustrates the therapeutics applicable to this affection according to those views. It embodies a principle. This case is a paralytic affection from a concussion of the spine. The patient, a strong healthy man of forty, was thrown from his horse, and fell with much force on his posteriors. He soon complained of violent pain in the lumbar region, darting pains down the thighs, and want of sensation and numbness in the lower extremities, with coldness; the right leg least affected. The pulse was small and slow. Ten ounces of blood were taken away, and an embrocation applied to the loins.

On the 23d of September, 1786, the day after the accident, he was found to have no inclination to pass water, and the bladder was found in a flaccid state extending to the navel. Three pints of dark urine were drawn off by the catheter, assisted by pressure on the abdomen; 18 grains of calomel were given in the course of the day, in two doses, with a strong purgative mixture.

On the 25th, 20 drops of laudanum having been given the evening before, a greater degree of sensation was observed in the limbs. The water was still removed by the catheter and pressure; the motions were involuntary.

From the 26th to the 30th, the same treatment being applied, with 20 or 30 drops of tinctura lyttæ every eighth hour, the symptoms continued the same. This state, indeed, was unaltered, except in regard to occasional difficulty from indurated feces, requiring to be scooped out, to the 8th of October. The tinctura lyttæ being then given in drachm doses, the pulse became more frequent, and the sphincter ani contracted.

Urine, during this time, occasionally flowed involuntarily; but the case continued in a state of very slowly progressive improvement, with one drawback, namely, the

recurrence of involuntary evacuations on a blister being applied to the sacrum.

But on the 8th of October, a change was made in the treatment, in this respect, that all stimulants were laid aside, and the opiates, with certain antispasmodics, exclusively relied on; namely, sulphuric æther, and sagapernum. Under this class of remedies, we are told that "the stools and urine became regular and voluntary, the pulse became stronger, and the sensation of the lower extremities increased. The patient perceived no other sensible effect from the medicine than a degree of drowsiness, and having continued it to the subsequent January, he had no complaint left."

This case recommends to your consideration a principle which may be stated thus:—That in the forms of palsy which have the same relation to those ensuing on vascular fulness or rupture, which loss of power from concussion bears to that arising from compression, medicines presumed to influence primarily the solids of the system will probably have a more remedial agency than those which operate immediately on the blood-vessels; or, to state this principle in a more practical form, sedatives and antispasmodics will be more effective than stimulants or depletory measures.

The following case will further illustrate this principle:—Elizabeth Smith, æt. 68, of a muscular form and apparently a strong constitution, having for several previous months been inadequately nourished, and having felt a diminution of power in the right side, fell down in the street, and about a week afterwards was brought into the St. Marylebone Infirmary. From the time of this fall, which seemed not the result of any accident, she has been totally unable to stand unsupported, and had in a great degree lost the use of the right arm. Her bowels, she said, were generally either confined or irritable; the pulse not remarkable in character; her head entirely free from uneasiness.

From the 5th of November to the 3d of December, 1841, she was treated with aperients and the compound æther mixture of the Infirmary, and with one application of a blister, but to no advantageous result: occasionally some paralysis of the bladder manifested itself. She was then subjected to an opiate treatment. First, a scruple of Dover's powder nightly, then two grains of opium; the bowels being regulated by mild aperients, and having a disposition to diarrhoea, even under this practice. Meanwhile, her tongue became cleaner, and she obtained, first, comfort, then material improvement in the paralytic symptoms, the leg improving more slowly than the arm.

Much disposition to diarrhoea continued, and whenever this took place, the paralytic feebleness increased. Fermented stimuli

did not suit her; indeed her symptoms were ameliorated just in proportion to her freedom from diarrhoea, and her steadiness in the use of the sedatives.

To this effect of opium a contrast may be observed in a case, the symptoms of which strongly suggested to my mind an hypothesis contrary to that on which the last case was conducted, namely, an hypothesis of compression from effusion.

A tall and moderately stout gentleman, æt. 64, of the nervous sanguine temperament, who, with much mental exertion, had indulged through life in very full living, had been visited from the spring of 1840 to the present time, December 1841, by a series of paralytic phenomena, preceded by a sense of fulness, vertigo, and oppression. He can walk for a very few yards, finds difficulty in pointing his feet, and stumbles over the smallest impediment. He complains of weakness in the lower extremities, and of general difficulty in changing their attitude; and is often visited by spasmodic twitches; his arms are merely weak. I saw this gentleman first in July 1841, and have since, with temporary good effect, and never with apparent ill effect, pursued a course of mild mercurial aperients, and small blisters to the nape of the neck. The general health of the patient, the appearance of his tongue, his countenance, and excretions, have been improving, with occasional fluctuations, up to this time, December 29, 1841; and the paralytic symptoms have been at least arrested in their progressive increase. It lately appeared to me expedient, as he was complaining of spasm and restlessness at night, to suggest to his medical attendant in the country that some form of morphia might be tried. To a letter recommending this I shortly received the following answer:—"On the morning after the first dose of one-third of a grain of muriate of morphia, with half a grain of calomel, the patient reported an improved night; but on my next visit, I learnt that in the course of that morning the lower extremities had become perfectly useless, continued so for 48 hours, and were only recovering their accustomed state when he was next seen."

The different results of the use of opium will be remarked in these two cases: on the high-fed valetudinarian, on whom palsy had been advancing gradually, with the evidence of antecedent cerebral congestion, and in the very different case previously described.

The following case will present a difficulty certainly not appreciated by the author whose views I am illustrating, in the application of a sedative treatment to the nervous phenomena of palsy: it arises probably from the complication, in the same person, of such pathological states with those of compression.

The patient, æt. 60, of a bilious tem-

perament and sinewy frame, was brought into the St. Marylebone Infirmary, having had, the day before, an attack of hemiplegia of the left side, with loss of voice and distortion of mouth, which had subsided in about two hours. His voice was still, however, thick, and he complained of vertigo. In the course of the day of his admission he had two similar attacks; and it was found that these attacks were repeated daily at about the same hour. The pulse, during these attacks, was sluggish and incompressible. Eight ounces of blood had been taken from his arm before I saw him; and two days afterwards, I directed cupping to the extent of six hours, with some doses of calomel and jalap. Having thus relieved his system, with, as he said, improvement of his general feelings, I was induced, by the intermittent character of the daily attacks, to prescribe five minims of Liquor Arsenicalis in camphor mixture, three times daily: three grains of calomel were given every night. This plan having been continued three days with no effect on the paroxysms, I was next led by my observation of the effect of sedatives on the nervous forms of palsy, to give him, one night, ten grains of Dover's powder. The paroxysm came on the next morning, with unusual heat of head, but it did not subside; it continued, indeed, for four days, and did not begin to subside until his gums were affected by repeated doses of calomel, which I gave, having first applied some leeches to the temples. His articulation then returned completely, but not so the use of his limbs. From this time, indeed, to the present moment, Oct. 24, 1842, a period of four months, the disorder has not resumed its intermittent character. During that time, the power of articulation has never left him; but the paralysis of the extremities is continuous, though now gradually obtaining some diminution under the use of strychnine. The leg acquires power more rapidly than the arm.

The continuous duration and increased severity of the attack, which followed, in this case, the dose of Dover's powder, must, I imagine, be considered as probably referrible at the time to that measure.

I have thus sketched, and endeavoured to illustrate, what appear to me important views relative to apoplexy and palsy, leaving to another lecture certain modifications to which, I apprehend, these views are liable. It may, perhaps, be asked, what addition is made by these views of that subject to previous science? How far the assumption that a form of apoplexy and palsy exists set up by other causes than vascular fulness, or effused blood, or serum, is either new or practically valuable? and whether, in the period so rich in medical inquiry which has elapsed since 1792, the deficiency, if it ever

existed, or if any was left by Dr. Kirkland, has been obviated? Certainly many authors have protested largely against excessive depletion in apoplexy, and have advanced instances in which the brain has, on examination, afforded no evidence of congestion on either serous or sanguineous effusion. But neither before that time had this subject been as clearly brought out as by Dr. Kirkland, nor since that time, though often adverted to, has it received adequate investigation.

The Greek physicians, generally, were humoralists in their pathology of apoplexy, though their humoralism took generally a wider range than that of the moderns. It is not, according to Hippocrates, vascular fulness or effusion alone that leads to apoplexy, but a superabundant or vitiated state of any one of his four humors—bile, atrabile, pituita, or blood.

The pneumatic school, founding its views partly on a supposition that a certain subtle aura was distributed by the arterial system, was likely to avail themselves of the machinery which this hypothesis supplied in accounting for such affections of the cerebral organs. This aura, indeed, was a vitalising principle, whose subtle nature would render it, in their philosophy, susceptible of affections from *moral* causes. Accordingly, the antecedents of apoplexy enumerated by Arctæus, the most eminent luminary of that school, comprise emotions of the mind, terror, despondency, great and unexpected pleasure, *γελως ασβεστος*, phenomena, the operation of which must be, in the language of our times, primarily on the nervous system.

In modern times, vascular fulness or rupture has been the great antecedent of apoplexy, modified, indeed, relatively to the extent of depletion indicated, by a theory, not of possible apoplexy from other causes, but of varying extent and kind, in that fulness or effusion which has been assumed as a cause. Such were mainly the views of Boerhaave and Vansweten; and that these views were entertained by the great pathologist with whose case I have opened this discussion, is sufficiently evident; and such were also the views of Frederick Hoffman. This eminent person, in dealing with physiological or pathological causes, certainly improves upon the theory of Stahl, who had gone no further than to impute the phenomena of living matter to the agency of a mind,—a proposition which, though possessing the utmost abstract truth, does not advance science. Hoffman felt this, and took a further step. He assigned to the living solids an active principle as *inherent* in them, implying and implied; which hypothesis, no doubt, formed the basis of that theory of irritability afterwards conceived by Haller, and qualified by

the remark of Dr. Whytt, that no part is irritable, that is, without nerves.

With these views, it is somewhat singular that in the class of paralytic and apoplectic affections Hoffman should contemplate no other as affecting the subtle element, to which he assigns the brain as its material organ, than the affections of the vascular system.

Thus, in the 11th section of his 7th chapter "De Hemorrhagiis," he will be found estimating the passions of the mind in their reference to the causation of apoplexy, as producing spasms, which disturb the general circulation just as a crumb of bread dropped into the trachea is seen to produce them. It would have been a more compendious and simple hypothesis to allow the mental affection to influence *immediately* the cerebral substance, and to occasion at once a stasis there. This assumption would better explain the causation of those apoplexies in which the stroke apparently occurs with no antecedency of vascular derangement, and in which, I may add, much relief ensues from abstraction of blood after the stroke, though very little or no appearance of plethora or congestion have preceded it.

Dr. Cullen's systematising and comprehensive mind could hardly fail to suggest another class of antecedents to these affections, than vascular compression or effusion. He thinks it probable, to use his own words, that "apoplexy does not always depend upon that cause, but sometimes upon a certain state of immobility of the nervous power, produced by certain circumstances in the nervous system itself, which seems to be communicated from one part of the body to another." But in regard to treatment, "many of these causes," he observes, "are so powerful, and thereby so suddenly fatal, as scarcely to allow of time for the use of remedies; and such cases have been so seldom the subject of practice, that the proper remedies are not so well ascertained as to allow him to say more of them." His reference to the more gently operating causes under this head is brief and unsatisfactory.

Dr. Darwyn was nearly cotemporaneous with Dr. Kirkland. His psychological views disposed him to apply to apoplexy a principle of distinction analogous to that of Dr. Kirkland, but far less practically developed: he expressly speaks, indeed, of oppression from congestion, or from effused blood, as only *one* of the causes of apoplexy.

It is interesting next to observe how far the subject of apoplexy, as considered abstractedly from vascular derangement, is taken up by that eminent investigator of the present day, Dr. Abercromby. "When a person," he observes, "previously in perfect health, falls down suddenly, deprived of

sense and motion, and dies, after lying for a certain time in a state of apoplexy, and when, on inspection of the case, we cannot discover in the brain any satisfactory deviation from healthy structure, this is the affection which I propose to call simple apoplexy." The force which the word "simple" seems to convey with it in this instance is, that the apoplexy so described is viewed by the author solely in relation to its phenomena, and not to any presumed cause.

That no hypothesis in regard to treatment suggested itself to this acute observer, as founded on the distinction here adverted to, is evident from his allusion to the treatment which these cases actually met with. He only, indeed, observes on this point, that they were treated "in the usual manner," an expression which certainly appears to recognise but one principle in the treatment of apoplexy. This mode of speaking almost appears to suggest, that the physician who used it had overlooked the consideration, to what an extent disease *is*, what treatment renders it? The therapeutical question is, in some sort, a part of the pathological.

If, finally, we ask ourselves how far the necessity of such inquiries as we have now entered into is superseded by the researches of the present day, I know no better way of answering this question, than a reference to those valuable Cyclopædias of medical knowledge which the last fifteen years have supplied us with.

The article Apoplexy, in the Cyclopædia of Practical Medicine, gives us considerations on this subject exclusively humoral; though Dr. Clutterbuck's great practical experience has occasioned him to lay down many practical rules limiting the extent of depletion, even on the hypothesis that vascular fulness or rupture is the great general antecedent of apoplexy: and thus he would be found, in many cases of that disease which a more enlarged hypothesis would term "nervous," using the same precaution in regard to depletory agents, which this latter supposition might suggest.

Very considerably more complete and comprehensive are the views afforded us by Dr. Copland, in his masterly article "Apoplexy:" he indeed adverts to a form of apoplexy designated nervous by authors; but when he gives his own estimate of this species, he reconciles it with a theory of *pressure*, as the recognisable antecedent to that state, in such a manner as not to leave any very definite grounds for a practical distinction. Thus, on this subject he entertains an hypothesis respecting the ganglial apparatus supplied to the encephalon as affecting its vascular system, and thus producing retardation or rupture. But the recognisable antecedent to the apoplectic state, will, in this point of view, still be retardation or rupture: for we

know too little of the functions of the ganglial nerves supplied to the brain, to assert or imagine a time for *their* operations in such a presumed sequence; though we might consider ourselves authorised to imagine that in many cases of apoplexy, those peculiarly which originate in moral causes, the affection of the encephalon itself, the organ of mind, is primary, and the affection of the vascular system of the encephalon secondary, rather than to entertain the reverse view.

We must not, I admit, indulge ourselves in speculating with Frederick Hoffman upon a propulsive force in the membranes of the brain as circulating a nervous fluid, or assume a knowledge of this subject analogous to that which we possess of the motions of the blood, as a groundwork for our pathology. Indeed, it is almost to be feared, that, possessed as we are of a completed theory of the *vascular* circulation, we may be tempted to speculate upon its agency in the causation of disease further than is warranted, and thus leave out of view the nervous system as originating morbid actions.

The following comprehensive remark, made by Dr. Copland, in his general account of the condition of the brain in apoplexy, seems to bring *his* vascular and nervous form of the disorder under a common category. "The various states" he observes, "of vascular impulse and action, impeded circulation in the veins and sinews of the brain, and distension of its capillaries, whether arising from the influence of the organic nerves or the blood-vessels, or from morbidly increased action from obstruction in the large veins, the lungs, or the right side of the heart, will either individually or in partial conjunction occasion the above effect, *i. e.* the phenomena of apoplexy, owing," he adds, "to the unyielding walls of the encephalon."

This statement will not propel us far on our way towards a theory of apoplexy as resulting from an emotion of the mind. The views, indeed, contained in the excellent article to which I advert, are sufficiently pronounced in favour of a nervous form of apoplexy to stimulate our curiosity,—sufficiently indeterminate to authorise our affirming that, as far as they are concerned, that subject is unexhausted.

I have been led, by the topic which I have chosen, to enter largely into the views of an acute and learned author, whose work, published sixty years ago, is now rarely or cursorily adverted to. I know not how I may have accomplished, or be accomplishing my purpose; but I am assured of its intrinsic usefulness,—namely, the giving weight to certain bygone views, which appear to contain the germs of hitherto unexpanded distinctions in a most important branch of pathaology. In my next lecture I shall proceed further into this subject.

MEMOIR ON
 ABRASION OF THE DIARTHRODIAL
 CARTILAGES BY FRICTION,
 AND ON THEIR
 ATROPHY FROM OTHER CAUSES.

BY ROBERT KNOX, M.D.

[Concluded from p. 178.]

(*For the London Medical Gazette.*)

WHILST joints giving rise to these reflections successively appeared either in the Practical Rooms or in the hospital, and were examined with more or less care by me, there occurred one of those cases which seemed to go far to explain satisfactorily the whole of the phenomena. This occurred in 1826, or early in 1827, and, if I recollect right, a brief account of the case was read to the Medico-Chirurgical Society in Edinburgh; and after the lapse of ten or twelve years, a second, and still more remarkable, one occurred, amply, as I imagine, (for wherever a theory exists, it behoves the surgeon to speak with every caution,) confirming my former views. The details of these cases I shall take the liberty of giving at some length. Of the other numerous specimens now before me, drawn from my own pathological collection, I shall say but little: nor is it necessary. The condition of the joint, in one and all of them, was predicted previous to dissection. They were stiff half-flexed joints, partially, as it were, though, in some cases, but slightly, ankylosed, if such a phrase could be applied to them. In fact, many of them seemed to be stiffened merely by malposition, or rheumatism; but, be this as it may, the absence of the cartilages of encrustation was predicted, and found invariably to have happened.

CASE I.—I select purposely the two extreme cases: they prove the theory best; and they seem to me least complicated with extraneous matter. Were I to select one of the numerous preparations before me of knee-joints taken from aged persons who had long laboured under a stiff half-bent knee-joint, and in whom, after death, it was found that the cartilaginous surfaces of the femur, patella, and tibia, were partially gone, it might with great propriety be said, a joint like this proves nothing as to the cause of the disappearance of the cartilages: they

may have been absorbed by some pathological condition either connected with themselves or the subjacent bones, the joint may have sustained some injury, a blow, sprain, or have laboured under chronic rheumatism: there may even have existed at one time inflammation of the cartilages, and their disappearance or absorption may have caused the semiflexed and stiff joints, and not been caused by it: but in Cases 1st and 2d, it will not be easy to apply this mode of reasoning in explanation of the appearances I shall now describe.

The knees of a stout and sufficiently well-made person were observed just before dissection to be slightly but obviously bent; both to the same extent, or nearly so: the flexion could easily be rendered greater, almost as much as is usual, but by no reasonable force could the limbs be extended. I predicted that on dissection there would be found an absence of the cartilages of encrustation at many points, and the bone probably polished or eburnated: this I did from a previous knowledge of such joints, but I was not at all prepared to explain all the appearances. The joints were examined with every possible care in the presence of a large class of students, and the preparations are now before me. The trochlea or pulley of the femoral condyles was much altered in shape: the outer one had lost its cartilage of encrustation, and acquired an ivory polish in some places; at others the texture of the bone had been worn into: the inner condyle had lost its usual breadth, and had acquired a peculiar exostotic deposit overlapping the shaft: the hollow for receiving the elevated ridge of the patella was greatly changed, its natural form having become narrow and twisted: the patella can scarcely be described, so irregular has it become: the cartilage of encrustation is entirely gone, and the bone either worn into or polished: two new osseous deposits have formed, seemingly in the tendon of the crureus muscle, one above and the other at the inner side of the patella; so that if the investigation had been carried no further the case might easily have passed for one of fractured patella, with subsequent chronic inflammation, and absorption of the cartilages. But such an opinion subsequent and previous inquiry had taught me was totally void of truth; the real cause of all these

changes being at the back of the joint, behind and somewhat above the inner condyle, in the form of a foreign body (free cartilage), about the size of a large bean, resting on the condyle, altering its nature, and closely wedged in betwixt the osseous surface and the synovial membranes, and in such a way as obviously to have been immoveably fixed in that position for a considerable time. The pain caused by this cartilage had led to the semi-bent position of the limb, as being the one best calculated to relieve the distress. In this position the cartilaginous and previously floating body had become fixed, or, perhaps, grown there originally, although it did not adhere by any pedicle when I examined the limb; and this malposition and altered form of the knee-joint led to all the pathological appearances I now describe.

FIG. 1.

I had almost forgot to mention, that the inner condyle of the tibia had begun to shew exostotic depositions, and a small one may be seen on the anterior portion of the upper spines of the tibia. The opposite joint resembled the one I have just described in all respects. But it is by no means unlikely that some pathologists might be inclined to ascribe what I here most confidently trace to a mechanical cause, to other causes—such as rheumatism, or inflammation, or to the same cause, whatever that might be, which led to the formation of the free cartilages. To meet these objections I shall detail my “second case.”

CASE. — A young man met with a severe burn a considerable time ago over the ham and back and upper parts of the leg, and this, in healing, caused a strong and permanent flexion of the limb at the knee-joint, so as to resemble greatly the usual contracted and anchylosed condition of this joint after some recoveries from white swelling. As the limb was thus greatly shortened, he required the use of a very high-heeled-and-toed shoe or boot. The cicatrix following the healing of this troublesome burn was extensive, hard, and placed transversely about the lower part of the popliteal surface; but, having thus partially, at least, recovered from this serious accident, he resumed his usual, and, to him, as it proved, dangerous, occupation of a groom, or horse-breaker. In a few weeks after, the horse he rode fell with him, by which accident the cicatrix in the leg was torn open violently, and an extensive and, as it proved, an incurable sore rapidly spread over the entire calf of the injured limb; and there being no likelihood of his recovering from this second accident so long as the limb was allowed to remain on, it was removed, in a few days after the accident, by Mr. Fergusson, by amputation in the usual way and place above the knee-joint, or a little above the junction of the lower and middle third of the thigh. The brief description of the amputated limb is as follows:—

1. The sore or ulcer, which was the immediate cause why amputation was resorted to, was an ill-conditioned and most extensive sore, reaching fully two-thirds down the back of the leg. On cutting into this longitudinally, with a

view of exposing by dissection the deeper structures, it was found that the posterior tibial nerve (internal popliteal of some writers) had been involved in the cicatrix, so that, had an attempt been made to have cut out this cicatrix previous to the second accident, with a view to the removal of the contraction and forced flexion of the joint, a portion, at least, of this nerve must have been cut out by the operator. This was the opinion of all those who were present at the dissection.

2. The flexors of the leg (semimembranosus, tendinosus, and biceps) had suffered but little from the disuse of the limb, or rather joint. The gastrocnemius, on the other hand, together with the solens and popliteus muscles, had degenerated into firm pale cartilaginous masses, in which it was not easy to trace any remains of muscular fibres. The great artery and vein lay in their usual places, at a considerable distance from the surface. I ought to have mentioned that, by the first accident, the knee-joint had been contracted nearly to a right angle.

On tracing the extensor muscles (cruræus, vasti, and rectus,) from the upper edge, where they had been divided at the moment of amputation, downwards towards the knee-joint, it was found that, on approaching the knee, the tendon usually, in appearance at least, united, could readily be separated into two distinct portions, a superficial and a deep: the superficial followed its usual course towards the patella and over it, to become continuous with the ligamentum patellæ. The changes in the structure of the deeper and stronger portion of the tendon were remarkable: in its substance, and placed immediately above the original patella, was another, fully as large as the original one, developed in the centre of the tendon of the cruræus, and lined on its articular aspect by a portion of the tendon itself; this again was invested by the synovial membrane of the joint. This singular structure, which was, in fact, an accidental or abnormally formed patella, had evidently been developed in the tendon of the cruræus muscle as a consequence or result of the limb having been used or walked on when in a contracted or flexed state; and yet there could scarcely have existed any accidental fibro-cartilage in the tendon to

serve as a basis for this newly-formed sesamoid bone. Many surgeons have thought that by unusual friction abnormal synovial capsules may be, and are, formed; to this another fact must now be added, viz. the accidental formation of abnormal sesamoid bones as large as the patella, seemingly originating in mere mechanical change in the form of the limb, and that too, though not preceded by any fibro-cartilage, heretofore considered as an essential preliminary stage in such formations*. To return to the further examination of the limb.

In that layer of the united tendons of these muscles which lay over the one I have just spoken of, and which, in fact, could be easily traced to the muscular fibres of the rectus, to which, indeed, it belonged, I found another small bone or patella developed, placed immediately over the regular patella; and lastly, on the fore part of the shaft of the femur, a few inches higher up, there existed what at first appeared to be merely an exostosis somewhat larger than a walnut. The saw of the surgeon had gone through this exostosis, as a portion merely of the femur, during the amputation.

Before describing the many interesting points made out by a vertical section of the preparation, I may first mention some other circumstances connected with the second accident; that, I mean, which led to the removal of the limb. Although not suspected during life, the heavy fall from the horse had fractured the bones of the leg in several places; one fracture ran through the malleolus externus into the joint; another ran obliquely through the tibia, commencing about three inches above the ankle-joint: it proceeded first across the spine of the tibia, then twisting spirally so as to reach the posterior surface of the bone, it also penetrated into the joint; higher up there was a most distinct longitudinal fracture or fissure in the tibia, moving upwards for about two inches; some blood was effused into the ankle-joint. None of the ligaments were torn; and my notes merely further add, that not the slightest displacement had taken place in any of the fractured portions; so that their detection during

* As the examination proceeded, it was found that the new-formed patella here spoken of was composed of two portions.

life, or in any other way than by dissection, seemed impossible. The cartilages of encrustation in the ankle-joint were of a deep red colour; but no laceration could be detected either in them or in the investing synovial capsule.

A vertical section of the preparation was now made: this extended from the point where the femur had been divided by the surgeon quite to the middle of the tibia, and of course traversed the knee-joint vertically and mesially, dividing at the same time into nearly equal parts the original patella, all those of new formation, and the exostosis on the shaft of the femur.

This examination gave the following results:—The exostosis on the front of the shaft of the femur had at one part united completely with that bone, so as to form, as it were, but one; a common periosteum surrounded them: but at another, and that a very considerable portion, it was easy to shew, by the presence of muscular and tendinous fibres betwixt the femur and the new growth, that the latter had been formed first in the centre of the tendon of the cruræ; that, in fact, it was of the same nature, and owed its existence to the same causes which produced the accidental patellæ; that it had grown to the femur, and not from it. The bone in question, which I have hitherto called an exostosis, was simply an elongated accidental patella, formed in consequence of the altered form of the knee-joint, and of the unusual pressure and continued extension of the muscles: as these causes continued to operate, and even to increase so long as the limb was used in that altered form, the soft parts between the new-formed bone and femur were absorbed, and the elongated accidental patella becoming firmly and inseparably united to the shaft of the femur, might thus in time have been mistaken for an exostosis growing from the bone, instead of to it.

I cannot refrain from believing that this preparation is one of much interest, and calculated to extend our views in respect to the formation of new bone under a variety of circumstances. Here a bone forms in the centre of a tendon, having interposed between it and the shaft of the femur, tendinous fibres, cellular and adipose tissue, and periosteum. By and by all

these tissues are absorbed or disappear, the new-formed bone grows to the original femur, becomes identified with it, is covered at last by the same periosteum, inclosing both as if they had always been but one bone. An inspection of the preparations, or of the accompanying sketches, will, I feel assured, convince every unprejudiced reader that I have described accurately the history of this new and singular formation of bone.

As the patient died some days afterwards, an opportunity thus offered of examining the entire shaft of the femur, and of tracing fully out the effects of what I must always consider as merely mechanical causes. Exostoses have usually been described as growing from the bones; and no doubt they generally do; but I am prepared to prove that they occasionally grow *to* the bones, and were at first formed in certain tendons or soft parts at least, whose original tissue permits of a ready change from tendon to bone; and this seems peculiarly the case with the extensors of the leg, or cruræus, vasti, and rectus muscles.

FIG. 2.

Fig. 2. Longitudinal section of a part of the upper portion of the fe-

mur: the lower end, in short, of the part connected with the head of the bone being the portion through which the surgeon's saw passed. It displays the extent to which the osseous deposit had proceeded, to within a distance of about three inches from the trochanters. So high as it went, it proved its origin from tendinous fibres. (Fig. 3, B.) This sketch shews the

FIG. 3.

extremity of the same section (A and B) before it was divided longitudinally, contrasted with A, which is merely the section of a healthy femur: *a* the linea aspera; *b b* the old shaft of the femur; *c c c* new bone laid over the old shaft; *d* periosteum; *e e* soft parts, portions of the cruræus and extensor muscles, generally filling up the space between the old and new bone at this point, similar to what may be seen upon the other sections; *f* a dense cartilaginous mass growing in and filling up the medullary cavity of the old shaft. Nothing of this kind existed on the surface of the exostosis; there never, in fact, having been any medullary cavity in it. On the exterior of the old shaft those changes had commenced which usually take place after amputations, and which have been so well described by Scarpa and others; but they had proceeded to no great length: ten days only having intervened between the period of amputation and the death of the patient.

Before quitting the knee-joint, to seek for further illustrations and proofs of the correctness of these views in other joints, I may very briefly allude to five or six specimens collected in my museum of contracted joints, with whose history we were not so well acquainted. The difficulty in deciding on the exact nature of the pathological phenomena these joints present arises from the obstacles in the way of clearly discriminating between cause and effect. When we lay open a contracted-semiflexed joint, bent to an angle more or less approaching a right angle with the femur, and find the cartilages of incrustation abraded, broken up, a great part of them gone, the bone bare, polished, or deeply worn into, as if it had also suffered from abrasion, the form of the osseous surface of the condyles, patella, and tibia, singularly altered, &c. it is of course difficult to decide on cause and effect, since the contracted state of the limb may just as readily have been caused by and followed the disappearance of the cartilages (from some unknown cause, as atrophy, rheumatism, chronic inflammation), as the contraction may, by altering the form of the joint, have given rise to these changes. For my own part I feel disposed to think both views may be correct enough, applicable merely to different cases; but all that I have myself seen leads me to a belief in the efficiency of the cause I have assigned, and to give it a preference—viz. a mechanical change in the form of the joint.

Description of the knee-joints of a middle-aged male brought into the Practical Rooms.—Both joints were permanently but slightly contracted. In the right knee-joint a free cartilaginous body was found, under the tendon of the popliteus muscle, where a distinct sesamoid bone may also be felt. The foreign body could be pushed into the joint, and so made to disappear in the general cavity. The cartilaginous body was observed previous to the joint being fully laid open on the front. On this being done, the cartilages of incrustation were found to have been abraded, or, at least, to have disappeared from a considerable portion of the tibia immediately within the external lateral ligament of the joint. One half of the corresponding semilunar cartilage had also disappeared, and the

surface of the tibia had an ivory polish over all that surface from which the cartilage had been rubbed off. The corresponding condyle of the femur had suffered changes quite similar to the tibia, but, in addition, there was a deep hollow in the centre of the condyle, as if the friction, after destroying the cartilage, had commenced wearing away the bone. The cartilaginous incrustation of the patella had begun also to break up, and the shape of the bone to alter: the trochlea of the femur had also suffered, both in its cartilaginous and its osseous textures: the margins of the femoral condyles have become elevated and project. In the other knee-joint similar changes were found, but not to the same extent. No free cartilage was found in this joint; and in neither could be detected the slightest trace of purulent deposits, adhesions, or other symptoms of an inflammatory or ulcerative process.

A preparation in the museum, marked 1157, shews the extent of injury which may be produced, even to the osseous texture, so soon as the cartilages have been abraded or absorbed, in the event of the bones not becoming eburnated, which sometimes happens. In this case (found in the dissecting-rooms), besides abrasion of the cartilages, the articular surface of the outer condyle of the tibia has been worn down into a deep excavation of at least 3-4ths of an inch in depth; and its outer brim, in connection with the fibula, had given way, as if fractured. Unless the abrasion, then, be arrested in its progress by the process of eburnation, the bones themselves speedily suffer, as I have frequently observed. The knee was slightly contracted, but the history of the case is unknown. The adjoining bones are brittle and spongy.

1160 is an interesting preparation, but a verbal description may suffice to explain it sufficiently well. On that part of the inner condyle of the femur which plays on the corresponding surfaces of the tibia and its semilunar cartilage, there is an elevation of about an inch in length, and about the sixth or seventh of an inch at its greatest elevation. This seems to have interfered with the motions of the joint, and, by throwing the action chiefly on the external condyle, the cartilage has been rubbed off it (the joint being stiff and contracted), and from off the cor-

responding condyle of the tibia. On both surfaces, wherever most exposed to the friction, the surfaces have taken on a very perfect ivory polish, with the usual grooves and elevated lines on the surface. The remaining surfaces had begun to shew that they were influenced by this change: the patella begins to lose its shape, the tendinous attachment to the bone begins to ossify, the edges of the condyles of the tibia and femur to enlarge, become rounded, and to overlap the shaft; and the superior spines of the tibia are becoming irregular, elevated, and generally altered.

There is another preparation extremely similar to the above, but the changes of the osseous surfaces have gone further: I shall call it No. 1700. Its history I cannot find in my notes, but I feel assured that it was put up to illustrate the effects of abrasion and destruction of cartilage and bone in the knee-joint, and that there was a foreign body loose in the joint. The outer condyle has broadened out by an osseous deposit, so as to accommodate itself to the altered form of the joint, and to meet the changed position of the patella. The inner surface of the femoral pulley has proportionally narrowed.

In the stiffened knee-joint of an aged person (1701) there is even a deep hollow worn in the condyle most exposed to friction, although the adjoining part of the bone had commenced taking on the ivory polish. The cartilaginous covering of the patella and its opposing pulley had begun to suffer by abrasion. Thus it does appear that, in certain persons, a permanent alteration in the form of the joint, will, by altering its healthy action, give rise, by mere abrasion, or by the absence of all pressure, to a destruction of the cartilages of incrustation of the synovial membranes and of the bone itself, unless arrested by the timely change into the ivory structure*. The hock-joint in the horse frequently presents all these changes of loss of cartilage, porcelainous deposit, &c. The grooves on the astragalus, caused by the friction, have been mistaken for canals or reservoirs to hold the superfluous synovia.

* The ivory or porcelainous deposit is not confined to the mere surface on all occasions: in the first dorsal and last cervical vertebrae of the camel the change extends deeply towards the centre of the bone.

During the autumn of last year I happened to visit the museum of Dr. James Douglas, of Glasgow, and was much struck with an interesting case of diseased knee-joint, the details of which I had better give in his own words:—

DEAR SIR,—I have your note this morning, acknowledging receipt of mine. I hasten to fulfil the request contained in your note of Tuesday. I asked permission of the gentleman by whom the preparation was sent to the rooms (Mr. Lyon, one of the surgeons to the Infirmary), which he at once granted, to make use of the case.

An old man died of gangrene of the feet, after fever, Feb. 1842. One of his knees was removed to examine a fractured patella, which had resulted from a violent exertion many years before. He had never submitted to treatment for it, so that the pieces were about an inch and a half separate, and when he walked, he used to fall, from the knee bending under him.

Knee-joint was found full of pus, from inflammation developed in it, since his legs became gangrenous. The two portions of the patella must have grown considerably since the fracture, for each is nearly as large as an ordinary patella, the growth having taken place from the broken edges, and having rounded them, both from before backwards, and from side to side. The inferior fragment was attached to the tibia by its ligament, which was weak, and perforated with holes, probably in consequence of disease, and from the low inflammation which had been going on long in the joint. The upper fragment had the extensor muscles still connected with it, but from long disuse they were in a great measure converted into fat at their lower part. The lower edge of this fragment is firmly attached to the fore part of the femur, immediately above the commencement of its articular surface, by a thin, but broad and strong ligament, completely closing the usual communication between the lower part of the knee-joint and its upper expansion, which is frequently called the suberureal bursa. The cartilage is partly removed from this portion of patella, and the roughened part is connected to the front of femur by fibrous adhesions.

Chronic inflammation seems to have

been long going on within the joint. What remains of the cartilage on the ends of the tibia and femur has a swollen and fibrous appearance, and on the edges has a hole as if marked with the teeth of a mouse which had been gnawing it. From the notch of the femur, and some parts of the condyles of the tibia, the cartilage is quite removed, while the bone in some parts remains unchanged; but in others a degree of hyperostosis is going on. On other parts, where the bone is exposed, but where mutual pressure was made on it, the porcelain deposit has gone on to a considerable extent. On some parts of the femur, not articular, this deposit is going on in rounded agglomerated masses, with smooth surfaces. Some of these are still soft on the surfaces, admitting of being cut with the knife.

On the back part of the joint, and in connexion with the cervical ligaments, where there are naturally loose fimbriæ or fringes of the synovial membrane, there are several smooth cartilages, some round, like peas, and others convex on one side, and concave on the other, adapted to their situations, hanging loose into the joint, attached only by the slender duplicature of synovial membrane.

I look on this preparation with interest, because it confirms the view which I advocated in the *MEDICAL GAZETTE*, within the last year or two, about the origin of loose cartilages in the joints, illustrated by a preparation marked P. 29, in my museum, where there is a loose cartilage in the cavity of the tunica vaginalis, and another growing from the tunica albuginea still covered by the serous membrane.

Hoping that this may be of use to you, I remain,

My dear Sir,

Yours very truly,

JAMES DOUGLAS.

235, George Street, Glasgow,
March 12, 1842.

P.S.—I forgot to say that you may make any use you please of this case.

Dr. Knox, Edinburgh.

It were easy to extend this list with reference to the knee-joint, by describing numerous similar preparations in the museum; but leaving the matter in the hands of others, I shall conclude by a few remarks on the joints of the upper extremities.

Numerous specimens of diseased elbow-joints in my own museum illustrate perfectly the effects which an altered form of the joint produces on the cartilaginous and other tissues: the shoulder-joint presents a somewhat more complex subject of inquiry, as being combined with an inarticular tendon, whose pathology has by no means been made out.

In 1827, I published in the LONDON MEDICAL GAZETTE an account of several dissections of shoulder-joints which had evidently suffered some severe injury during the life of the person. What these injuries were could not be conjectured, as the dissections occurred merely in the Practical Rooms; but after considering all the appearances carefully, I ventured to draw the conclusion that in some, at least, there had been rupture or dislocation of the bicipital tendon within the capsular ligament. Soon after the publication of the Memoir alluded to, Mr. E. Stanley published in the 3d vol. of the same journal an account of some cases in which he suspected rupture of the tendon in question: these cases he considered as illustrating my dissections, and as being, in fact, the complementary part of my memoir, which, for the reasons assigned, I had it not in my power to publish. But still there remained this difficulty, that I had described dissections of joints with whose previous history I could not be acquainted, and Mr. Stanley had published the history of certain cases in which injury had been done the shoulder-joint, and rendering it probable that the injury was really a rupture of the tendon in question, but *unaccompanied by any dissection*, his patients having recovered easily from injuries unaccompanied by other serious lesions. As far, then, as regards dislocation of the long tendon of the biceps, the question remained pretty much as left by Portal, who considered it possible, and cited, as the most remarkable instance of it with which he was acquainted, the case of Louis XV. who, by a fall from his horse, had injured the shoulder-joint, which injury left a stiffness and intolerable pain, unalleviable by the most distinguished surgeons of the day. A quack bone-setter was at last reluctantly called in, who, by violently twisting the arm in all directions, relieved the King at once

from all stiffness in the joint, and from that agony which he had suffered for weeks previously. Portal states as his belief that there had been dislocation of this tendon, and that it had been reduced by the bone-setter. Boyer, on the other hand, points at the case, and criticises the statements of Portal as being totally unsupported by any pathological dissection on record. If I rightly understand that most distinguished surgeon, he denied the possibility of such an occurrence. In respect to rupture of the tendon by an accident, I do not find much notice taken of it until subsequent to the publication of my Memoir in the GAZETTE. Some eight or ten years afterwards, Mr. Adams, of Dublin, I think, read a brief notice to the British Association, if I rightly recollect (for I speak merely from memory), having a reference to the pathology of the shoulder-joint, but he took up a very different view of the matter from either Mr. Stanley or myself. He seemed to think that the occasional absence of the inter-articular portion of the tendon of the biceps was owing merely to rheumatism and ulceration, however induced, or atrophy. Now although I feel fully convinced that in certain of the dissections I had described, a rupture of the tendon within the joint had originally happened, I feel much disposed to coincide partly with Mr. Adams's view also, as applicable to other cases, or at least to his modification of it, that injuries might be inflicted on the joint, leading to the gradual softening and disappearance of that part of the tendon in question, altogether independent of any rupture. Both views, in short, appeared to me compatible with each other. Since then, I learn from a paper in the 24th Vol. (2d Series) of the Medico-Chirurgical Transactions of London, by Mr. Soden, that a paper had been published in the 14th Vol. of the GAZETTE, by Mr. G. Smith, on the "Pathological Appearances in Seven Cases of Injury of the Shoulder." On examining this paper by Mr. Smith, published in 1833-34, and therefore seven years subsequent to mine, it seems that the cases were all like my own in this respect, being without any previous history of the case during the life of the person. Suspicions might be entertained fairly enough, that in some

the appearances were entirely *post-mortem*, and in others partially so: nor is the eburnation of some of the surfaces any direct proof to the contrary. Thus the question of the possibility of a rupture and of a dislocation of the tendon of the biceps remained nearly where it was. A case of dislocated tendon is quoted by Mr. Soden from the *Encyc. Method.* as quoted from Mangel; but the case is said not to be a clear one. Mr. Hargrave's case is mentioned also, of a subsequent date; so, likewise, are those of M. Dupuytren and Sir A. Cooper. It is admitted by Mr. Soden that most of these cases, whether of rupture or of dislocation, are extremely imperfect. Mr. S. gives two cases of dislocation of the tendon; if they were clear to Mr. Soden, and his coadjutor quoted in the paper, Mr. Richard Partridge, they are, by no means, to the reader. There are two cases mentioned, and there is but one woodcut, which corresponds precisely to neither description. One of the diseased joints seems to have been sent to Mr. Partridge for his examination and opinion thereon; but it is not stated which was sent, so that the reader is left in doubt and conjecture as to an essential part of the history of these cases. The following statement is placed underneath the woodcut: "Front view of the preparation in King's College Museum, shewing the displacement of the biceps tendon from its groove, and the head of the humerus drawn upwards and forwards in contact with the acromion and coraco-acromial ligament." Now one naturally asks, what preparation is this? for there is no mention of any such in the body of the paper; and so we are left to conjecture that Mr. Soden had presented *one* of the diseased joints to that museum. But this is a mere conjecture on my part, for no where is this hinted at, neither is it said to which of the cases it belonged.

It would seem (or at least I gather from the heading of the paper) that Mr. Soden's notes and brief history of the cases had been sent originally to Mr. Partridge to be read to the Medico-Chirurgical Society in London, and that Mr. Partridge had added thereto some remarks of his own. Some observations on these remarks I have put into a note; the whole matter is unworthy the running text, but still it

may serve to explain to the reader one at least of the circumstances which have a tendency to mystify and confuse many medical histories which, if stated fairly and candidly, would be intelligible to the plainest capacity*.

On looking over the MS. catalogue of my museum, I have observed, since writing the above, one or two cases of dissections, made several years ago, which seem to bear on this very obscure matter—I mean the pathology of the shoulder-joint, and of its inter-articular tendon.

Fracture of the anatomical neck of the humerus.

In an aged female subject, during the course of a careful dissection of the shoulder-joint, a fracture in the anatomical neck of the humerus was observed. At what period the accident had happened which led to this could not be ascertained, but the broken bones had not united by any osseous deposit. The fracture was within the capsular ligament, and likewise, in a great measure, within the synovial capsule. The surrounding muscles had not, apparently, sustained any injury, being all sound both in respect to their tendons and muscular parts: even the long tendon of the biceps was untouched, and perfectly healthy in every respect. The joint showed no appearance of ever having been inflamed; the cartilage of incrustation was sound.

Ruptured tendon of biceps.

December 1836.—Since my first communication regarding rupture of the tendon of the biceps, several facts and observations have occurred to me which

* If Mr. Soden had himself read Mr. Stanley's paper in the *MEDICAL GAZETTE*, 3d Vol. he would have seen the reference made, in the *first instance* by Mr. Stanley, to my Memoir, and farther, the remark (I quote from memory, not having the volume before me) that I was the first who had drawn the attention of pathologists to this subject. The omission of all mention of the *earliest memoir* on the pathology of the biceps tendon, I ascribed, not to Mr. Soden, but to Mr. Partridge, who, true to his class (Londoners), was bound to strike out any view or circumstance in any memoir of mine not of London growth. Some of his colleagues go even further than this, as may be seen by a reference to a zoological work published lately by one of them, wherein, amongst numerous other amusing mistakes, the cranium of the porpoise, or piked whale, has been mistaken by this profound comparative anatomist for that of the mysticetus. All this comes from trying to make use of property which does not belong to the person.

may possibly still further elucidate this obscure subject.

On dissecting the right shoulder-joint of a stout muscular man, the long tendon was observed to present its usual strength and structure until a short way after entering the bicipital groove of the humerus; or, in other words, where it came in contact with the synovial capsule of the joint. Here it suddenly diminished to about a fourth of its usual thickness, and appeared likewise altered as to structure. Having reached the top of the groove, it adhered to the adjoining parts of the capsule and to the tuberosities, and could not be traced into the joint. In every other respect the joint was healthy, and presented no appearance of having been at any time dislocated. The cartilages were every where as healthy as in a young person; so that, if the altered state of the tendon of the biceps, and its total disappearance within the joint, is to be attributed, as some have done, to the pathological condition called by the French pathologists "*usure*," and by some "*absorptio senilis cartilaginum*," here is evidently a case which cannot be forced into this category. The age of the person seemed to be about thirty, and with the exception of the absence of the tendon of the biceps within the joint, there could not be a healthier joint in any one*.

Secondly, on conversing with Mr. F., he reminded me of a preparation found in the dissecting-room a few years after I communicated my original paper to the *MEDICAL GAZETTE*. In this case the long tendon proceeded no further than the groove, and the portion within the joint did not exist.

From these circumstances the very probable conjecture was formed by Mr. F., that this had been a case of dislocation of the joint, with rupture of the bicipital tendon; that the dislocation had been speedily reduced, but that the tendon had not re-united.

How far this view is supported by

facts drawn from the history of unreduced dislocations I am unable to say, but may here remark, that in the dissection of an unreduced dislocation of the shoulder-joint, evidently of considerable standing, the biceps tendon, although stretched and out of its groove, was not ruptured; the tendon of the supra-spinatus muscle had been somewhat injured, but not torn through; the capsular ligament was of great strength, and entire, enclosing, as usual, the head and neck of the bone, which rested on the subscapularis muscle. The circumflex nerve had been partially if not wholly lacerated, but had reunited; the deltoid, a good deal wasted, and beginning to alter, presented a remarkable ridge running from the acromion process to humeral attachment of the muscle. These were the principal appearances noticed; to which may be added, that the glenoid cavity had still a cartilaginous covering, but was partially filled up.

Partial dislocation of the tendon of the biceps flexor, with rupture of some of its fibres.

The right arm of a muscular male subject, aged 66, dissected in February 1837, threw much light upon the question of ruptured tendon of the biceps. In this arm the capsular ligament and all the parts connected with the shoulder-joint were quite healthy, with the exception of the tendon of the biceps. This tendon was about double its usual breadth where it corresponds to the groove of the humerus: about half of the tendon lay in the groove, and the remainder partly on the inner crest, partly on the side of the smaller tuberosity of the humerus. The part of the tendon which lay in the groove was sound enough, but that which played during life over the crest and smaller tuberosity was fretted, its fibres as it were worn through, ruptured, and spread out; so that in a short time, as it appeared to us, or on any violent motion of the joint, the tendon would have given way altogether, and would thus have constituted a case of ruptured tendon of the biceps within the synovial capsule. The surface of the tuberosity over which a part of the tendon had played was rough, not being covered with any soft parts or cartilage; and this, in the most evident manner, had been the cause of the wearing of the

* This case is remarkable as being entirely without any other morbid alteration; those previously seen by me being all more or less subject to the objection which has since been made to the view I originally took of such cases, viz. that the altered condition of the tendon uniformly coincided with an affection of the synovial membrane and cartilages of incrustation, and that these were attributable, first, to old age, or, secondly, to rheumatism. Now the above case happened in a comparatively young person, and the joint was perfectly healthy.

tendinous fibres, and the destruction of its synovial membrane. Being without any history of the person during life, it can only be conjectured that, at one time or other, and perhaps but a short time before death, he had experienced a dislocation of the tendon: this gave rise to its new position, its spreading out, and its partial destruction. It is worthy of particular notice, that the organic changes were limited exactly to what I have stated, and that the cartilages of incrustation belonging to the joint were quite sound and of their usual thickness.

It was upon this subject, and in the same extremity, that my brother noticed an unusual laxity of the scapulo-clavicular joint; the acromial end of the clavicle rising fully three-quarters of an inch above the *acromia scapulæ*. May not this person, then, have received some violent injury, displacing the tendon of the biceps, and luxating the joint spoken of, and even perhaps the shoulder-joint? The tendon of the biceps may not have recovered its original position, and, by being then exposed to friction, must, at last, have ruptured with little or no effort beyond the usual motions of the joint. We have here, then, a second case in which the tendon must indisputably have been ruptured altogether independent of the accidents of old age, called by French pathologists "*usure*" of the cartilages.

After what I have said, it will not, I trust, be supposed that I doubt the history of "*atrophy of the cartilages*" of the knee and other joints, as described by others. The removal of these structures, whether effected by vital organic changes within themselves, as many suppose, or by being acted on by the neighbouring tissues, as was Mr. Hunter's opinion, is a question I do not propose entering on. It is foreign, to a certain extent, to the object of this memoir.

I may now allude to other joints with a reference to these views and opinions. The cartilages of incrustation disappear from the acetabulum and head of the femur under a great variety of circumstances; and occasionally, but by no means so frequently as in the knee-joint, it has appeared to be owing to the effects of abrasure, and of unequal pressure and friction on the opposing surfaces. But there are

difficulties here calling for more extended inquiry. The following suggestions are respectfully thrown out for the consideration of the "critical inquirer into truth:"—Why the hip-joint should not present abrasure of the cartilaginous surfaces so frequently as the knee when its state of motion is altered, may be owing to this, that the motions of the joint are not so easily affected, in one sense, as those of the knee-joint. But I have very often, in looking carefully into the joint, found the cartilage thinned, and even broken up, at points where, at first, and on a hasty glance, the structures seemed unaltered. In cases of interstitial absorption of the neck of the thigh-bone, the cartilages of the joint always appeared to me much altered. I am aware that Mr. Gulliver, one of the most distinguished pathological observers of the present day, has given two cases of interstitial absorption of the neck of the thigh-bone without any accompanying alteration in the form or texture of the cartilages; and many more (though not of equal value) might be added to these; but the difficulties accompanying such cases could, I believe, be explained away. That one limb may be shorter than another, whether from an acquired or a congenital deformity, and yet the cartilages remain entire, appears to me explicable enough. If the limb retain most of its motions at the hip-joint, the cartilaginous surfaces are as much exposed to the due degree of pressure as ever. Should time permit, I shall return to this subject in a short appendix. Mr. Gulliver's memoirs merit the deepest attention from all surgical pathologists.

The little notice I have taken of contemporary writers, and of the standard pathologists of the present and past age, has not arisen from any overweening confidence as to the accuracy of my own views, but solely from a want of the necessary leisure to do so. The difficulty also of procuring many valuable works proves a great obstacle to the entering on bibliographical inquiry, at least in this city. Nor can it, I hope, be necessary to caution any but the very young surgeon or student that the views here brought forward, in respect to abrasion of the cartilages under certain circumstances, have a

reference solely to those circumstances, and are by no means intended to be applied to those other cases of destruction of cartilage by other causes—such as inflammation, ulceration, &c. The whole subject connected with the *disappearance* (I use this word to avoid any theory) of cartilages of incrustation, together with their synovial investing membrane, and not unfrequently the destruction of bone itself in joints where neither inflammation nor ulceration seems ever to have existed, merits an extended inquiry from surgeons and pathologists. In respect to *atrophy* of the cartilages as a disease *sui generis*, its possible occurrence seems undoubted: still, its whole history is involved in difficulty. A modified theory might, perhaps, reconcile both views. Let us suppose that to allow of abrasure or usure of the cartilages of a joint there must be present a peculiar condition of the cartilages themselves—a softening, in fact, caused by constitutional or other causes: it is by no means improbable that such a state occasionally happens.

Some good practical surgeons, however, seem to me to deny altogether that there is such a pathological condition as “usure,” abrasion, or even atrophy of the cartilages; ascribing, apparently, all such phenomena to inflammation, ulceration, &c. This seems to be the opinion of Mr. Syme*, judging from his silence in respect to such conditions of the cartilages. On the other hand, Mr. Liston admits the existence of atrophy of the cartilages as a pathological condition of the articular cartilages altogether independent of any preceding inflammatory or ulcerative process. His chapter on hypertrophy and atrophy of the cartilages is exceedingly practical, and merits the careful perusal of surgeons and pathologists.

CASE OF

ENLARGED BRONCHIAL GLANDS PRODUCING DEATH;

WITH REMARKS.

By Dr. GOLDING BIRD.

(For the Medical Gazette.)

ELIZA BURMAN, æt. 16, an exquisitely strumous looking girl, was admitted, under Dr. Bird's care, in July 1842, at

the Finsbury Dispensary. She had been the subject of extreme dyspnoea for several months, attended with but slight cough, and a scanty mucous expectoration: her nights were restless, and frequently passed in the semi-cumbent position. She had lost a parent, and some collateral relatives, by consumption. She had never spat blood, and so far from having lost flesh, was decidedly stout for her age: menstruation was regular. During the preceding year, the cervical glands on the left side had become considerably enlarged, and formed an elongated irregular lobed tumor, involving the parotid gland, and extending from the left zygoma to the clavicle, producing extreme deformity. The whole mass felt hard and unyielding to the touch; it had no superficial redness, and presented no tendency to suppuration.

On examining the chest, there was slight but decided flattening beneath the right clavicle; and there, as well as over the whole of the right chest, percussion elicited a dull sound. The respiratory murmur was replaced by bronchial respiration in the infra-clavicular and scapular regions, whilst in the middle and inferior parts it was puerile; the expiratory murmur was distinctly audible in the upper part of the chest, and the vocal resonance increased. Over the left chest, percussion produced a much more sonorous sound than was natural, remarkably contrasting with the right side; still the respiration was imperfectly audible, and in the upper part was bronchial. The heart appeared healthy.

There could scarcely be a doubt on the nature of the affection under which this girl laboured. The existence of tubercular deposit in the right lung was evident; the state of the left was less satisfactory: the probable existence of emphysema was, however, sufficiently obvious. The only doubt that could arise was as to the deposit in the lungs being of a malignant character, from the state of the cervical glands which existed; but the progress of the case, and the absence of the pink sputa, to which attention has been drawn by Drs. Stokes, Addison, and Cowan, removed all suspicion on this head.

Gradually the dyspnoea increased; the respiration became less and less distinct in the left side, which still retained its sonority on percussion; and

* System of Surgery.

some evidence of cerebral congestion appeared. The frequent dull, heavy headache; the noise in the ears; the flushed face, most marked on the left side, all bore witness to a state of brain explicable by the impeded return of blood from the head, from the pressure of the cervical glandular tumors. Shortly after some stupor appeared: from this she rallied sufficiently to be enabled to take some little exercise; when at last, after taking cold, dyspnoea became distressing, and she sank early in September, without emaciation, cough, expectoration, or any of those signs which mark the closing scene of the victims of consumption.

At the post-mortem examination the head was not opened. In the chest there were no pleuritic adhesions; the right lung was nearly solidified by the copious deposition of crude tubercles, scarcely any having advanced to softening; no cavity existed. The left lung contained much fewer tubercles, and was distended by emphysema; the bronchus on that side was completely flattened, so that only a very narrow fissure existed, through which air could pass. The cause of this pressure was found in two large bronchial glands, each nearly two inches long, between which the flattened bronchus was placed. All the lymphatic glands of the chest and abdomen were found exceedingly enlarged. On dividing the large bronchial glands, they were found full of white caseous matter, and free from any trace of the grey or black matter so frequently met with.

The heart was loaded with black blood, and the vessels turgid. The enlarged cervical glands had so far diminished since death, as to present no approach to the extreme deformity they produced during life. The body presented no appearance of emaciation.

REMARKS.—This case affords an example of a circumstance of occasional occurrence, viz. of a case in which copious tubercular deposit exists, not sufficient *per se* to destroy life, and ending in death before the commencement of any disorganizing process. There can be but little doubt that in this instance the immediate cause of the fatal termination was the constriction of the left bronchus by the bronchial glands, so as to prevent ingress and egress of the air to the left lung, the right being so full of tubercles as to

be incompetent to the task of arterialising the blood. The cerebral symptoms which preceded death, all indicative of congestion going on in the brain, are, I conceive, readily explicable by the pressure exercised by the glandular cervical tumor on the vessels of the neck. It is true that the pressure on the left bronchus was not sufficient to absolutely exclude all ingress of air, for after death a chink-like opening existed; still, when it is borne in mind that the enormously distended state of the cervical glands disappeared with the cessation of life, it is but fair to presume that a similar state of things might obtain in the case of the bronchial glands; and that although these were not found on the dissection so distended as to completely close the bronchus, still it is very probable that such might have been the case in the last hours of life, and then these bodies might have subsided in the same manner as the cervical glands.

I have now seen three other cases, in which death occurred in the course of phthisis, where the disorganization existing was not sufficient to account for the fatal termination, and in which pressure on the left bronchus existed; in two, the constriction formed was produced by enlarged bronchial glands, and in one by an aneurismal tumor. The state of the glands, to which I am anxious to draw attention by the publication of the above case, has scarcely been mentioned by authors as a cause of death; and M. Louis, who refers to the frequent occurrence of enlarged bronchial and cervical lymphatic glands in tubercular phthisis, mentions it only as a pathological fact, not appearing to regard it as an occasional cause of death. In like manner Morgagni, in his laborious production on the Seats and Causes of Diseases, repeatedly mentions the presence of enlarged bronchial glands; but in no instance do they appear to have been so increased in volume as to have pressed upon the bronchi.

Regarding the diagnosis of this state of the bronchial glands, I may remark, that I have only met with it in phthisis, and then always connected with enlarged cervical glands. The post-mortem examination of this case throws some light on the cause of pulmonary emphysema. This has been explained on different hypotheses; and one that

has been very frequently taught is, that the cells of the lungs become distended by the mechanical violence of coughing. Here, however, the cough had been but slight, often quite absent, and never violent; there was, however, constriction of the bronchus: to this, therefore, the explanation adopted by Dr. Stokes well applies. Air at each inspiration could enter the lung in greater abundance than the succeeding expiratory effort could succeed in expelling. It is true that the stricture of the bronchus would equally interfere with the entrance and escape of the air; but then it must be recollected that as the muscles subservient to inspiration are far more numerous and powerful than those of expiration, it follows, that whilst a muscular effort sufficient to draw air into the lung past the constriction could be easily accomplished, the following effort at expiration would only be sufficient to drive but a moiety of the inspired air through the flattened branches; and the result would be, what was found after death, a permanently dilated and emphysematous condition of the pulmonary cells. This hypothesis exceedingly well explains the condition of lung almost constantly met with in children who die with lungs studded with tubercles; there is almost always an emphysematous state of the cells of such lungs, sufficient indeed, as I have more than once seen, to make the diseased side the most resonant on percussion. Here the pressure of the tubercles on the bronchial ramifications produces the same effect in distending the air-cells as the pressure on the bronchus in the case above narrated. The frequent occurrence of emphysema with tubercles in the lungs of children is directly opposed to the statement of their never occurring together, on which is based an empirical mode of treating phthisis, adopted by some few practitioners, who endeavour to induce emphysema by making their patients breathe through either long curved tubes, or short ones with a valvular plug in the centre.

One other fact is taught by this case, viz. that occasionally extensive tubercular deposit may exist in the lung without any marked emaciation. It is true that this constitutes the exception to the general rule; still, as it occasionally occurs, its cause is worth inquiring into. We know that the lung

has at least a double function to perform—one to burn off carbon, and a second to convert ordinary albumen into the self-coagulating form, or fibrin, which abounds in arterial blood. To effect these changes, it is necessary that the blood, whilst circulating in the capillaries of the lung, should be exposed to the influence of the air. If, therefore, this be prevented by the deposition of tubercular matter, or by the preternatural distension of the air-cells, so that there is left a diminished surface for the capillaries to ramify upon, it would necessarily follow that much carbon would be retained in the system; and ultimately the patient may sink from the effect of a poison generated in his own body, by the narcotic effect of a highly carbonized fluid circulating through the brain. If, on the other hand, the vital powers be less exhausted—if the lung is quoad its function less impaired,—then it is probable that some portion of that carbon which, in a perfectly healthy condition of the organ, would be *burnt off*, is deposited in the adipose tissues of the body, as one of the ingredients of fat. This might be hazarded as a probable explanation of the frequent accumulation of loose fat in the person of many an old bronchitic or emphysematous patient.

RESEARCHES

ON THE

NATURE OF TUBERCLES:

BEING PART OF A PAPER READ TO THE
PROVINCIAL ASSOCIATION

BY WILLIAM ADDISON, Esq., F.L.S.

THE elements of the blood visible by the microscope, without any manipulation, are—

1st, The red corpuscles; 2d, the colourless corpuscles; 3d, molecules and granules in the interior of the colourless corpuscles; 4th, similar molecules and granules isolated in the liquor sanguinis, and independent of the corpuscles; 5th, the fibrine, which may be seen by the microscope coagulating in the form of delicate cylindrical fibres, having a diameter even less than that of the molecules.

The fibrine does not form globules or corpuscles of any kind. Molecules, granules, and colourless corpuscles,

enveloped in a net-work of fibrinous fibres or filaments, with variable quantities of entangled serum, form the entire mass of the buffy coat of the blood.

The phenomena displayed on the addition of liquor potassæ (Brandish's alkali) to the blood corpuscles are very remarkable: the first effects of the fluid are very rapid and energetic; after a short time, by following the directions given in the paper, the alkali may be observed slowly diffusing itself among the corpuscles. The red corpuscles may be seen to explode and disappear instantaneously, or to burst open gradually, and discharge their contents, and many singular changes of form may be witnessed. The colourless corpuscles may be completely and slowly dissected by a proper application of the liquor potassæ—all the stages of the process and the number and nature of their contents may be readily seen by the microscope. For this purpose, a drop of the liquor sanguinis from the surface of buffy blood is removed by the point of the finger, and transferred to a slip of glass, previous to coagulation; it should be spread out a little on the glass, and the liquor potassæ cautiously added from the point of a pen-knife or a lancet, while the corpuscles, without any covering, are under examination. This manipulation, with a little practice, may be readily accomplished with one of the small upright French microscopes, and by moving the slip of glass gradually forward, the progress of the alkali may be watched for some time. Rapid changes take place; molecules and granules are developed in the interior of the corpuscles, which enlarge by imbibition, and then dehisce or explode, the molecules and granules pouring out of them in great numbers; if the alkali be acting weakly, the molecules swell to granules, and the granules enlarge previous to their final disappearance by dissolution in the liquid.

Pus corpuscles differ in no respect from the colourless blood corpuscles, except only as they are altered in size and appearance by exhaling their own contents, or by imbibing the fluids with which they are associated. Water and the dilute acetic acid cause them to enlarge, developing the molecules and granules in their interior. The effects of the liquor potassæ upon them are

very singular and instructive. On the application of this liquid the corpuscles immediately begin to enlarge by imbibition; a great number of granules become exceedingly conspicuous within them; finally, they burst open or explode, and the granules are dispersed around.

Several cases and experiments are minutely detailed in corroboration of the foregoing statements, from which the two following are selected:—

Case of Shingles.—One of the clear transparent vesicles was opened with the point of a lancet, and a great number of colourless blood corpuscles was found by the microscope in the fluid. Many of them exactly resembled the corpuscles in the blood; others appeared a little shrivelled, and a few were remarkably large. All of them contained molecules; the large ones had several bright granules, which, on close inspection, were evidently moving within them—that is, the granules disappeared in one part of the corpuscle, and became visible in another. This was repeated several times during the observation, apparently from the working (“*writhing*”) or undulation of a fluid, which, by alternately dividing and coalescing, and then again dividing, formed the granules, which were sometimes visible at one spot, and then at another. The author has seen similar phenomena in the inner vesicle of the red corpuscles after the addition of a drop of gum water.

A little water was now added to the corpuscles from the point of a lancet; after a few minutes the shrivelled corpuscles became quite plump. Liquor potassæ was afterwards added very cautiously in the same way, and the corpuscles, one after another, dehisced. At first they gave a sudden jerk, and enlarged to twice or three times their former dimensions, displaying the granules in their interior; and then they burst open by a kind of explosion, each corpuscle discharging about twelve large granules, which were gradually dissolved.

Case of troublesome catarrh (hay-fever).—Copious discharge of clear transparent fluid from the nostrils; a perfectly limpid drop of the mucus was examined by the microscope, and I was somewhat surprised to find in it a great number of colourless corpuscles, resembling the colourless corpuscles of

the blood. There were, indeed, corpuscles of all sorts, forming a complete series, with gradual transitions, from the colourless blood corpuscles through all the forms and varieties of pus corpuscles, up to large, round, granulated corpuscles and epithelium cylinders. My astonishment was great when I found most of these corpuscles provided with vibratile cilia in the most active state, so that some of the corpuscles were actually moving about by their means; and not only were the cilia in motion, but the molecules and granules in the interior of the corpuscles were in a very active state; they could be seen rapidly shifting their position within the corpuscles.

I examined no less than six different specimens of the mucus from the same individual, and I always saw a series of similar objects.

Case of Cancer of the Breast (existing some years).—Arm œdematous; the back of the hand had been punctured some weeks ago to relieve the swelling, and a serous fluid has been discharged from it ever since. The author frequently examined this fluid by the microscope, and always found in it a fibrinous coagulum, and corpuscles resembling in every particular the colourless corpuscles of the blood, somewhat altered by shrivelling. When the arm was cool and free from pain, the fluid discharged was perfectly limpid, as colourless as spring water, but corpuscles were found in it; and after standing ten or twelve hours, a delicate but almost invisible net-work of fibrine could be drawn out of it with the point of a needle. Sometimes the arm, without any obvious cause, became much more red, swollen, and painful, and then the discharged fluid had the appearance of ordinary serum; the number of corpuscles was much increased, and the coagulum was more dense. On the addition of water the corpuscles swelled out and enlarged; with liquor potassæ they burst open, discharging large granules. From the result of this and other experiments, it is evident that the serous fluids effused in dropsies differ from the serum after venesection; they contain fibrine and corpuscles. The fluid at the surface of inflammatory blood is the liquor sanguinis, highly charged with molecules, granules, and colourless corpuscles; it is a strong solution of fibrine.* The limpid fluids

discharged by œdematous swellings are of a precisely similar nature, with a less quantity of fibrine and a less number of corpuscles; the varieties of coagulable lymph are intermediate between the two extremes.

All abnormal discharges, and all the varieties of serum and coagulable lymph, are modifications of the liquor sanguinis—stronger or weaker solutions of fibrine. All the varieties of pus and lymph corpuscles are more or less altered colourless corpuscles—altered either by imbibing and growing larger, or by exhaling, shrivelling, and becoming less. In fact, all abnormal products are effusions, and not secretions.

The foregoing experiments (here briefly stated) are brought forward to strengthen the conclusion which it is the author's object to establish—viz., that all secretions take place in the interior of granulated vesicles or cells, not by transudation from one tube (a bloodvessel) into another (a duct); consequently that "tubercles in the lungs," "tubercular infiltrations," "hepatisation," and "pus," are not secreted products, but simply the elements of the blood effused by an excessive "vital turgescence" (or inflammatory action), having their peculiar characters determined by the texture and function of the structure, and by the amount of activity of the turgescence.*

A singular fact is stated with regard to the animalcules; it may be witnessed in all of them by the application of liquor potassæ (which the author calls his dissecting fluid). It penetrates the transparent tunic composing the body of the animalcule, by imbibition, and soon causes it to burst open or explode, precisely in the same way as the colourless blood or pus corpuscle; and the so-called stomachs of the creature are forcibly discharged, or thrown out one after another, thus becoming objects for minute microscopical scrutiny. The stomachs (?) swell and burst in like manner, precisely as the granules discharged from the lymph corpuscles of the frog, or from the pus corpuscle. These stomachs the author believes to be granulated vesicles, performing their functions by imbibition, and not by assimilating or digesting food, voluntarily

* The author refers to Mr. Goodsir's paper, and corroborates his opinion with respect to secretion.

taken. The vital powers of the animalcules are totally inefficient in opposing the imbibition of the poison, and their stomachs may be seen enlarging in the interior of the body prior to the rupture of the integument.

CASE OF ENTERO-EPIPOCELE.

To the Editor of the Medical Gazette.

SIR,

IF you think the following case of strangulated entero-epiplocele worthy of a place in your journal, it is at your service.—I am, sir,

Your obedient servant,

A. SUTTON, M.R.C.S.

Congleton, Nov. 1, 1842.

— Fisher, æt. 50, married woman, the mother of twelve children, residing at Somerford in Radnor, near four miles from this place, has been the subject of femoral hernia for about five years: has never worn trusses. On Tuesday, the 19th day of October last, whilst endeavouring to lift some heavy weight from the floor of her house, felt the hernia suddenly protrude with considerable force, and on examination found it to be much larger than on any previous occasion: had been down several times, but only on one occasion had she found it necessary to call in the aid of a surgeon; herself or husband having succeeded in reducing it. On this occasion the same means were used from about five o'clock P.M., the time of the hernia protruding, until about ten P.M. without any good effect, when I was sent for, and first saw the case at eleven P.M. same day. On examination I found a considerable tumor occupying two-thirds of the space between the right os pubis and inferior spine of the ilium on same side, extending in the direction of the inferior edge of Poupart's ligament. From the attempts which had been already made to reduce the hernia, the tumor had become tender and painful on pressure. Bleeding and the warm bath were had recourse to with considerable advantage, the patient being able to bear pressure on the tumor. The taxis was now tried, and with the usual auxiliary means, enemata, &c. persisted in for nearly three hours without any advantage. Cold lotions were ordered to be applied, and ordered to be continued until my return.

Considering a second opinion advisable, I requested my friend, Mr. Molart, of this place, to visit the case with me. On our arrival about ten A.M. of the 20th, I found the patient much the same as she was when I left her at three A.M.: pulse 100, weak; stomach irritable; considerable anxiety; tumor exceedingly painful when touched; integuments covering the tumor very much inflamed, with dark-red streaks appearing on the surface in various directions. Under these circumstances Mr. M. agreed with me in considering any further attempts at reduction impracticable, and only calculated to lessen the chances of a favourable result in the event of an operation being acceded to by the patient and her family—an opinion borne out by the sequel.

On apprising the patient and her friends of the nature of the case, permission was obtained, and the operation proceeded with.

An incision was made in the direction of Poupart's ligament along the superior portion of the tumor, about three and a half inches in length, dividing the skin and adipose tissue, and laying bare the crural fascia. The inferior lip was now divided at right angles to the first incision, and the flaps dissected back. A small opening was made in the crural fascia, a director passed right and left, and the fascia divided with the scalpel the whole length of the first incision. On cutting through some more cellular tissue, fat, and one or two small glands, a second layer of fascia was divided, as in the first instance, and the sac was exposed of a deep purple colour. At this period of the operation the finger was passed down to the crural arch, which was divided by means of a probe-pointed bistoury, after which an attempt was made to return the hernia without opening the sac, which was unsuccessful. On opening the sac a large flap of omentum, enveloping a small portion of the ilium, was exposed, and, on endeavouring to return the intestine, a stricture was found at the neck of the sac, which was divided. The intestine, which was of a deep port-wine colour, with a few livid streaks interspersed, was, however, firm, and, after being released from the stricture, was returned into the abdomen. About two ounces of omentum was cut off, and the wound closed by

sutures. A piece of oiled lint was applied, and a fold of linen dipped in cold wash ordered to be placed over the wound. Some warm brandy and water was given, and the patient replaced in bed, expressing herself as perfectly relieved. Enemata were ordered to be given every fourth hour, warm fomentations to the abdomen, and in two hours after the operation Ol. Ricini ʒj.: to be repeated in the evening if the bowels should not be moved.

Same day, 7 P.M.—Pulse 90, soft; pain much easier; belly soft; stomach quiet; bowels firm.

Ol. Ricini ordered to be continued, and Mij. Ol. Croton. Sup. Sacch. Pauxill. to be taken immediately. Continue enemata.

20th, 10 A.M.—Pulse 100; stomach irritable; occasional vomiting; bowels obstinate; abdomen flaccid; no pain on pressure; wound healthy. Treatment same.

Enemata Ol. Ricini and Ol. Croton. to be repeated.

6 P.M.—Pulse 110 to 120; vomiting troublesome; stomach extremely irritable.

Cont. Medicamenta ut antea. Effervescing mixture ordered every fourth hour.

21st, 10 A.M.—Pulse 120, feeble; had a restless night; bowels still firm; stomach extremely irritable, rejecting all; hiccup; tongue slightly furred; belly soft, bears pressure; wound healthy.

Continue same treatment, and ordered calomel and opium every fourth hour in addition.

7 P.M.—Pulse 120, weak; hiccup; vomiting continues, becoming stercoraceous. Same treatment, salines, &c.

22d, 10 A.M.—Pulse 120 to 130; vomiting continues, extremely offensive; constant hiccup; great anxiety; bowels still torpid; belly soft, no pain on pressure; wound healthy.

Ordered brandy and water; continue salines, cal. and opium fomentations, &c.

Cont. Enemata with Ol. Ricini and Ol. Croton.

Did not see the patient in the evening, but received a message to say that the symptoms were the same, and the patient appeared to be getting worse. She continued in the same state, I was

informed, until near 5 A.M. the next morning, the 23d, when the bowels resumed their natural functions; copious evacuations took place, and when I visited her at ten A.M. all the unpleasant symptoms had subsided; pulse 90, soft and full; belly flaccid, no pain on pressure; wound healthy.

Continue salines only. Ordered anodynes.

24th, 10 A.M.—Patient continues doing well; had a good night; tongue clean; stomach quiet; wound healthy; complains of the purging, which has been rather severe.

Continue salines, with anodyne at night.

26th to 30th.—Convalescent; improving.

UTERINE HÆMORRHAGE, WITH RETENTION OF THE PLACENTA.

To the Editor of the Medical Gazette.

SIR,

I SOME time ago saw an article in one of the medical journals on a method of expediting delivery. I have forgotten in which publication it was, and have spent a great deal of time in looking for it, in order that I might refer to it in this communication, but have not succeeded. It was, however, to the effect that the author, in cases of protracted labour from inefficient pains, had found benefit from introducing two fingers into the vagina, and pressing against its posterior part during a pain, in imitation of the bearing down of the child's head on the perineum; and he attributed the good effects—no doubt rightly—to what is called the excitomotory function of the nerves.

I have not tried this plan previous to the birth of the child, but I have found it useful on what is, I think, a more important occasion—retention of the placenta from inaction, or insufficient action, of the uterus, especially when this is complicated with hæmorrhage. The following is an outline of one out of two or three cases:—

I attended Mrs. D. in labour about a month ago. She is the mother of a number of children, and her last four labours have been accompanied with flooding after the birth of the child. At her last previous confinement, two years ago, I was present, and the hæmorrhage between the delivery of the child and that of the placenta was

such as to cause debility, and greatly to retard her recovery. On the present occasion she was in a very weak state from an affection of the hip-joint, and, owing to the feebleness and inconstancy of the pains, the child was not expelled till a fortnight after the os uteri first began to dilate. After the birth of the child, gentle traction of the funis, and firm pressure over the region of the uterus, were made for some minutes, without inducing any uterine contraction; and as there was considerable and increasing hæmorrhage, I introduced two fingers into the vagina, and made firm and continued pressure on the perineum with them. The uterus commenced to contract the instant this pressure was applied, and the contraction continued till the placenta, together with some coagula, were expelled, when the hæmorrhage at once ceased, and the uterus remained properly contracted.

This is a very easy measure, which can be put in force in a moment, and need not interfere with any other efforts either to promote contraction of the uterus or to check hæmorrhage. I feel satisfied, however, that it may often be of service, and that it may occasionally obviate the necessity of introducing the hand into the uterus. The liability of tenesmus to induce premature labour, and the increase of uterine action from plugging the vagina, are, no doubt, physiological phenomena indetical with the one under consideration. I do not, however, propose that the above expedient should supersede the plug on any occasion where the plug is admissible.—I remain, sir,

Your obedient servant,

JOHN SNOW.

CICERO.

CHOICE OF A PROFESSION.

It is said that in Hindostan the members of every caste invariably adhere to the employment followed by their forefathers. In England, though it

is natural for a parent to bring up a least one son to his own occupation, it would rarely be expedient to do the same with half a dozen; and most fathers would be grateful to the friend who should teach them the advantages of the several professions, with which they are not experimentally acquainted. Mr. Hudson has undertaken the office, and in a short manual* has furnished information for parents of various grades;—from those who can afford the sum required for a commission in the Guards, to those whose humbler ambition is satisfied with a clerkship at an auctioneer's. Nay, even the state of hackney writer is explained, though it is confessed that "this employment is a sort of *pis aller* for a young man." By hackney writers Mr. Hudson does not understand the minor retainers of literature, but certain rapid penmen who wait in the public-houses about Chancery Lane, till their services are required by the law-stationers. Mr. Hudson is impartial and clear-sighted, and has drawn a judicious sketch of his subject, which will bear enlarging with advantage. Perhaps he has not laid sufficient stress on the predisposition or fitness for particular professions, which is generally manifest in the young. It would be too bold to say *jurisconsultus nascitur, non fit*, yet it is certain that at the age when professions are chosen, this predisposition is commonly so marked as to make some employments far more eligible than others. Nor are positive disqualifications to be overlooked. A dry abrupt manner would be a most serious hindrance to a practitioner of physic, in whom are required, according to an ingenious writer, "those qualities which may serve to render him an agreeable companion: for the family physician should always be the family friend."

No one, again, would think of recom-

* The Parent's Hand-Book; or, Guide to the Choice of Professions, Employments, and Situations, &c. By J. C. Hudson. Esq. 1842.

mending the law for a lad of less than average powers of comprehension. On the other hand, if a young man shows marks of decided talent, not measured by the fond partiality of relations, but by the stern gauge of schools and universities, if he is ready with tongue and pen, and ambitious of occupying the highest places in society, what profession can equal the bar? The business of an advocate consists, in great measure, in doing for the affairs of common life, what, according to Pope, Newton did for the theory of the solar system—all was darkness before, and he made all light. To disentangle truth from the confused statements of fools, and the wilful perversions of knaves, is his especial office. And as Bacon affirms that those who are “not apt to beat over matters, and to call upon one thing to prove and illustrate another”* should study the lawyers’ cases; so to those who are already gifted with this faculty of illustration, the bar offers its immense rewards. To such a man, adorned with such varied qualifications, we may boldly say—

I, bone, quò virtus tua te vocat; i pede fausto,
Grandia laturus meritorum præmia. Quid stas?

A parent fresh to the subject would not find it easy to make out from Mr. Hudson’s book why the medical profession is so ridiculously overstocked; for he affirms, firstly, that it costs a good round sum (toward which the student cannot earn a shilling) to get into it; and, secondly, that it takes time before an income can be obtained. Mr. Hudson, however, in the course of the chapter, solves this difficult problem, which seems a contradiction in terms; for if a profession is guarded by an expensive education, and years of dull expectancy after entrance, how can it be filled to excess? Such excellent *chevaux de frise* can be cleared off by well-mounted riders.

The problem is solved by giving the details on which it is founded. In the first place, then, what is the premium for a five years’ apprenticeship? “Independently of board,” says Mr. Hudson, “which is a matter more susceptible of calculation, the fee for a London practitioner, whose practice is moderate, say £300 or £400 per annum, is about £50, and it would not be very far from the truth to calculate the fee in every case in the same proportion to the annual value of the master’s practice.”

In the case supposed, therefore, the pupil, whom we may imagine to be living under his father’s roof, and feeding on the family joint, will learn the covenanted sciences at the rate of ten pounds a year. Then come the school fees, and the two diplomas, not very formidable *chevaux de frise* either. Mr. Guthrie, indeed, in a clinical lecture lately published in the *Lancet*, talks of these expenses in a tone of exulting regret, lauding himself for having contributed to make them small, yet not altogether pleased with them for being so low.

But we would ask Mr. Hudson, or rather, those parents whom he addresses, whether it is worth while to bind a son to a practitioner whose income is only £300 or £400 a year; and thus devote him, for at least three precious irrevocable years, to the slight opportunities of pharmacy afforded by so small a practice?

We think with Mr. Hudson that the acquirement of “a neat dispensing hand” is desirable: but this should be aimed at with a practitioner of many patients; or, better still, in a chemist’s shop.

Five years ago we gave the statistics of plucking at Apothecaries’ Hall, with a commentary*. Some pupils, as we there showed, are rejected from ignorance of anatomy, others from unacquaintance with the materia

* Essays. Of Studies.

* MED. GAZETTE, August, 5, 1837, p. 693-5.

medica; still more from a combined ignorance of several subjects. Of 106 plucked in one year, 36 were sent back solely on account of their ignorance of Latin. Not a few were unable to translate a single prescription; and, in short, every variety of defect was found within the limits of the subjects which form the curriculum of the Society. But we never learned, either from public record or private conversation, that Greek and Dynamics were among the topics of examination at Blackfriars; and we therefore think that Mr. Hudson frightens our budding practitioners needlessly, in what he says on this part of the subject.

It is a common thing in books of physiology to mention the force with which the heart circulates the blood, and the inquiry, "how great is the force stated to be," might be called a question in dynamics. So be it. But as to construing Greek, we suspect that many who pass a very creditable examination at the Hall would be sorely perplexed to know whether a Greek book was turned upside down or not.

It is generally stipulated, says Mr. Hudson, that during the fourth and fifth years of his apprenticeship the pupil shall be at liberty to attend lectures &c., All prudent parents, we think, will do well to stipulate that their sons be allowed to study their profession during a much longer period; as two years are insufficient to gallop through the lectures required by the Hall alone.

We agree with the author in his warning against those schools whose sole recommendation is their cheapness; but we cannot assent to his proposal, that the student should select a school for himself, by collating the advertisements which appear in the London papers during the month of September. If the recommendation could be followed, we should rather say, choose

a school as you would a tailor, or a wine-merchant, among those who do not advertise; but, alas! they are all tarred with the same brush, they all advertise! The only resource, therefore is, the advice of an honest and well-informed friend.

"There is no profession," says Mr. Hudson, "in which it is so difficult to make a beginning as in that of medicine; and there is too much truth in the vulgar saying, that by the time when a physician earns bread and cheese he has no longer any teeth to eat them with."

The same thing is popularly asserted of the Law. Yet as every young barrister is indulged with a brief or two during his first circuits, it is equally true that every physician or surgeon is entrusted with cases during his early years of practice. But to turn these exploratory fees rapidly into a handsome income is given only to the few men of talent *quos Jupiter aquas amavit*. If the beginner, however, sets up as a general practitioner, Mr. Hudson divides the problem into two cases. He first imagines him to have a private house, with a coloured lamp over his door, and believes it probable that twelve months will elapse before any body will put his services in requisition. So entire a lack of practice must assuredly be rare; and presupposes a want of that confidence which he ought naturally to have conciliated during his years of study.

Of course we coincide with Mr. Hudson in the opinion that an open shop is a more immediate road to practice. When such a shop, in a populous neighbourhood, is tenanted by a man of genial manners, the difficulty of making a beginning vanishes; and when we join this truth with the other fact of the £50 apprenticeship fee, we begin to see why the profession is overpeopled; a painful certainty, which,

under Mr. Hudson's original theory, was quite inexplicable. As for buying a practice, this is not quite so good as it seems; for "the new man will sometimes find that the patients have capriciously decided to transfer their troubles to the care of another."

"Capriciously," forsooth! To us the oddity is, that so many British freemen can consent to be bought and sold after this fashion. Do not they know that they are transferred to the new leech on the strength of the goodness of his draughts—not those in phials, but those on bankers?

On the whole, Mr. Hudson has pleased us much with his sketch, and we wish every success to his laudable endeavour to diffuse the important facts which form its basis:—

To know
That which before us lies in daily life
Is the prime wisdom.

BRITISH MEDICAL ASSOCIATION.

THE Sixth Anniversary Meeting of this Association took place on the evening of Tuesday, the 8th, at the British Coffee House, when the following address was delivered by R. D. GRAINGER, Esq.

GENTLEMEN,—The great object which this Association has with so much perseverance exerted itself to accomplish, has been so ably discussed, and so repeatedly considered in all its bearings, by several of the most distinguished members of our profession, that I have little hope either of extending your acquaintance with a subject with which those I have the honour of addressing are already so familiar, or of adducing arguments which possess the charm of novelty. Notwithstanding this, the present is so eventful a moment in the history of medical reform, that every individual, who is really desirous of securing the triumph of that important question, is bound to contribute his assistance, however trifling it may be, to advance the cause we all profess to advocate.

From the experience of the last session of Parliament, there can be little doubt that in the ensuing one the Government will bring forward some measures bearing upon the interests of the profession; and it may be reasonably supposed that the character of the changes proposed will very much depend upon the conduct pursued by the great body of medical practitioners. It is one among

the many evils requiring correction, that there is no acknowledged and legally-constituted body through which the legislature of the country can be made acquainted with the real deficiencies in the existing medical institutions, nor with the grievances of which the vast majority of our professional brethren have so long and repeatedly complained. In the absence of such a representative body, the duty of enlightening the legislature and the government has devolved on the various medical associations; and it is earnestly to be hoped that now, when the great problem which has engrossed so much of the attention of the profession is apparently approaching its solution, a combined and strenuous effort will be made in order that the exertions of so many years may not be rendered nugatory. In the observations which I have to offer it will be desirable to consider the question of medical reform in three points of view:—

1st. As it regards the education of the student.

2d. As it regards the rights of the practitioner.

And, lastly, as it concerns the public.

And, first, with respect to education, I may remark that this is a subject which has always been a prominent object of interest to this and other associations. Indeed, if we refer to the records of what has taken place since the subject of medical reform has been actively discussed, we shall find that individuals of all shades of opinion have united in the earnest expression of a desire to raise the standard of education to the highest point which may be found to be consistent with providing a sufficient number of well-instructed and enlightened practitioners for the wants of the country. That this is a desideratum yet to be attained, will, I believe, be doubted by few of those whose attention has been directed to the subject. I freely admit, what indeed has been universally conceded, that the Apothecaries' Company have made most successful efforts to promote this essential object, and that to the successive extension of their *curriculum* very large part of the advance made by the profession at large, in scientific knowledge, is attributable. As it is through the medium of this body that the great majority of practitioners enter the profession, its character and operations become objects of moment. Without indulging in any personal allusions, it is necessary to point out distinctly that neither the constitution of the examining board, nor the powers under which it acts, are calculated to realise what the spirit of the age demands. It is not becoming that the most important affair connected with a liberal profession should be entrusted to a trading company, nor that the only act of Parliament regulating medical education should compel a man of

science to commence his career as if he were entering upon a mere handicraft occupation, by a lengthened apprenticeship. The clause enforcing this apprenticeship of five years has been, in the estimation of those best qualified to form an opinion, the great barrier to the scientific education of the medical student in this country, and until it is entirely effaced from the statute book, all attempts to effect improvement in this way will be vain. It is, for instance, mainly owing to this clause that young men enter the profession at so early an age that there is not sufficient time for that preliminary education, the want of which has been so generally lamented. It is true, indeed, that the Court of Examiners, perceiving the evils of their own regulations, have recommended the student to devote a part of the period allotted to the apprenticeship, to the attendance on lectures, &c. ; but to my certain knowledge, in a great number of instances, this advice, from ignorance or other causes, is not followed. Repeated cases have been stated to me of young men having been occupied during the whole five years in the mere business of dispensing.

The apprenticeship clause is not only objectionable, for the reasons just stated, but it inflicts, as it appears to me, another and a more serious injustice upon the student, from which, it is to be hoped, he will be speedily relieved. The Court of Examiners, by extending the period of attendance upon lectures and hospital practice to three winters and two summers, without previously obtaining from the legislature a repeal of the apprenticeship clause, have virtually, in a great number of instances, compelled the pupil to be engaged eight years in the profession before he could obtain the license to practise. Now, when it is considered that four years is the longest period of study required in the most celebrated universities in Europe preparatory to taking the degree of doctor of medicine, the injustice of compelling the English student to devote twice that time in order to become a mere licentiate of a City company, is rendered conspicuous. When such a demand is made on the time and purse of a student, he has a just claim to the distinction which a degree would confer; and that such distinctions are eagerly sought after, is proved by the large number of young men who seek to acquire the diploma of the University of London. Last year as many as 80 students presented themselves for examination; and as the degree confers no legal title as to practice, it is clear, what my individual experience confirms, that the main inducement was the honour of belonging to a liberal and learned body. I know no circumstance more honourable to our profession than this fact, which in itself speaks volumes as to the want of a Faculty of Medicine in this metropolis. As it is, there is at present every thing to

discourage the noble aspirations after academic honours which clearly actuate a large number of the rising members of our profession; so that instead of finding the fostering care of a liberal institution to cheer him onward in the toilsome path by which alone scientific distinction is to be attained, the English student must make his way under every discouragement, and not only have his attention distracted by preparing for two or three separate examinations, but must incur an extra payment, which always presses hard on his limited resources, and but too often acts as an insurmountable barrier to the attainment of the honourable and legitimate object of his ambition.

I have been induced to dwell upon some of the evils affecting our junior brethren, because, from the nature of my pursuits, I have for many years witnessed the injustice under which they have suffered, and because, in the various pamphlets and addresses to which the subject of medical reform has given rise, this branch of the question has not received all the attention it merits.

So much has been written and said, touching the grievances of the general body of practitioners, whether surgeons or physicians, that I will only engage your attention a few moments whilst I point to a few of the more prominent causes of complaint. The whole of these may be distinctly traced to the indifference evinced by the governing bodies to the feelings and welfare of their members. The very circumstance of our meeting this evening, and the institution of so many associations throughout the empire, is a proof that those who have been invested with power for the protection of the profession, and for the advancement of medical science, have not faithfully discharged their trust; for the members of an active profession, whose incessant pursuits leave them but little leisure to engage in other matters, would not have devoted so much of their time and attention to the subject of medical reform, if they had not felt it to be an act of public duty thus to step out of their ordinary occupations, in order to rectify abuses from which both they and the community are the sufferers.

The complaints of the general members of the profession may be referred to two classes—one concerning privileges, the other respecting positive right.

The experience of the few last years has shown that a very general and growing feeling of dissatisfaction exists in the profession respecting the manner in which the Colleges of Physicians and Surgeons have exercised their powers; and when we recollect that the great body of members have been, and continue to be, pertinaciously excluded from all participation, both in the honours of the profession and the manage-

ment of its affairs, it requires but little insight into the springs of human action to perceive that so long as a system which is thus repugnant to every feeling of self-respect is persisted in, there never can be, and, what is more, there never ought to be, a cessation from every fair and legitimate means of opposition. Some persons may indeed consider these questions as unworthy the notice of scientific men; but we do not find that in other professions there is any indifference to such matters: the titles, dignities, and power attached to them, being considered as fair and honourable objects of ambition.

In the case of the College of Surgeons there is an additional and most just cause of complaint, that the ground of disqualification is made to infer a positive inferiority on the part of those excluded; the vast majority of English practitioners being represented to the public as forming a lower grade of the profession. In the scheme of reform lately brought forward by the Council of the College of Surgeons, it is understood that the same principle, which has hitherto been acted on by that body, was still recognized. Assuming this to be the case, it may be desirable to pause for a moment, and inquire what that principle is, which is thus so tenaciously retained. It is, as far as I understand, this—that the practice of medicine (as contra-distinguished from that of surgery) or of midwifery, disqualifies the individual so practising from all participation, even the most insignificant, in the honours or management of the affairs of the College. Now, gentlemen, I do not hesitate to say that no proposition could be conceived more injurious to the real interest of surgical science, than this attempt to perpetuate that distinction between medicine and surgery, which the unanimous voice of the profession has declared to be equally detrimental to the interests of both.

It is the highest glory of modern surgery, that, by medical treatment, the necessity of operations has been obviated in a vast number of cases, in which formerly the only hope of relief was in a painful mutilation; and all those who are anxious to alleviate the sufferings of our race would assuredly exert their power to encourage the practitioner of surgery to persevere in the same direction: least of all would they wish to see a retrograde movement, sanctioned by the authorities that be, towards the principles of those dark ages when medicine and surgery were divided between the monks and their barbers. At a time when all classes of medical men are, from conviction, agreed that there should be an uniform education for the surgeon and the physician, it is apparent that a plan which would disfranchise the great body of practitioners, and place the elective power in the hands of about two hundred of what

are called pure surgeons, would only tend to perpetuate those dissensions in the profession, which are, I believe, entirely attributable to misgovernment. It has always appeared to me a most difficult thing to comprehend how a body of honourable and distinguished men should ever support a system which deprives so many of their professional brethren of those privileges to which their education and scientific attainments so fairly entitle them; and still more, how this exclusion can tend to promote, as it has been asserted it does, the standing and respectability of the profession. I confess that, in my opinion, it would contribute much more to revive the honour and influence of the medical body in the estimation of the community, if, instead of the invidious conduct it has been our lot to witness and lament, the existing corporations had exerted the great influence they possess, to raise the standard of education, to protect the just rights of their members, and, specially, to cut from their number, as they would a tainted spot, those selfish empirics who only avail themselves of the title of an honourable profession to effect, with more deadly certainty, their unhallowed pursuits.

That the public rights of the great body of the profession are, at this time, almost entirely neglected, is proverbial. As I shall immediately have occasion to refer to the subject of illegal practice, I will in this place only adduce the treatment experienced by the general practitioner under the New Poor Law, in support of the above position. It is difficult to conceive that, if the Colleges of Physicians and Surgeons had publicly interfered when that measure was before the legislature, the obnoxious mode of appointing and remunerating the medical officers could ever have been put into operation. Even when the general attention of the profession had been called to the subject, we heard of no public remonstrances from the constituted medical authorities; and it was, I believe, mainly owing to the parliamentary inquiry, for which the profession is indebted to Mr. Wakley, and seconded by the reiterated remonstrances of this and other associations, that those ameliorations were effected, by which the rights of the medical practitioner and the claims of the poor have, to a certain extent, been established. It is the opinion of several gentlemen, who have paid great attention to this subject, that the Union districts are still too large; and I think that no true reformer can approve of the alteration which, in many cases, will enable the appointment of medical attendants to be for life. It would, in all probability, tend to a more active discharge of the duties of that important office, if the election took place every every three or four years.

In attending to the interest which the

public have in the question we are this evening met to consider, it would be superfluous in this room to adduce any argument to show how immediately the welfare of the community is affected by the degree of education which the medical practitioner receives; nor need I pause to point out that exactly in the ratio as the latter becomes enlightened does his power of dispensing good medicine increase. It may, then, be assumed that the highest interests of society are implicated in all that relates to raising the standard of professional education; and it is this consideration more especially which ought to induce the government of the country to take this all-important question under its immediate and earnest notice.

But the public are also affected in another great principle embodied in every comprehensive scheme of reform—the suppression, namely, of illegal practice. To expect, by any legislative enactment, entirely to suppress quackery, is, I believe, a vain anticipation; so long as there are knaves and fools in the world, will there be professions of cure by ignorant pretenders. Indeed, when we consider how numerous is still the class of incurable diseases, and the occasional success which attends bold and empirical practice, however much we may lament the fact, we can scarcely be surprised that, when science can hold out no hope of relief, the sufferer should sometimes catch at the confident promises of the undaunted quack. Knowing the strong feelings of the profession on this subject, I am dissident as to the correctness of my own judgment, but I certainly agree with those who, like my esteemed friend Dr. Hodgkin, think that all that can be effected by legal enactment is, in the first place to prevent the empiric assuming any title which he has not really obtained, so that he shall be compelled to write himself down a quack; and, secondly, he should be punished as for a misdemeanor, whenever his ignorance leads him into injurious mistakes, either of commission or omission. At the present time, however, no attempt whatever seems to be made to repress illegal practice; so that the empiric has a clear field before him. The only body which pretends to interfere is the Apothecaries' Company; and they, of late, appear to have abandoned this part of their duty as a hopeless affair; so that, unless some speedy and effectual change be introduced, there is great reason to fear that we shall lapse again into the state of the profession prior to the act of 1815.

I need add nothing to what has been already so repeatedly enforced respecting the great public advantage of a Board of Health, the want of which has been lately most strikingly illustrated in the interesting and able report of Mr. Chadwick on the

sanitary condition of the labouring population.

In conclusion, I may perhaps be allowed to occupy your attention a few moments, while I allude to some of the more important alterations which have been suggested in order to rectify the existing evils.

Those who have advocated the reform of the profession have been frequently blamed, by members of parliament and others, that although they had so much of which to complain, they were not agreed among themselves as to the nature and extent of the remedies required. I believe, however, that although there are some differences of opinion, they do not relate to what appear to be the essential points, upon which the great body of the profession are agreed.

The first great principle, which has commanded almost universal assent, is the incorporation of all legally qualified members of the profession. This principle was fully recognised by the delegates who met in London in 1841.

A second and equally important principle has been universally adopted by all parties in the profession, namely, that the education of every person proposing to become a medical practitioner, whether surgeon or physician, should be uniform, and carried to the highest point consistent with supplying the wants of the public.

A third principle, which may, I think, be regarded as essential to the ultimate success of all improvement, is that of the representative system—the governing body being elected by the legally qualified members. There is no doubt that this is one of the points upon which much difference of opinion will arise, and which will, in all probability, be opposed by the Government. When the important duties which would devolve on the Governing Council are considered, and especially when it is recollected that the interest of the community would, in various ways, be implicated in the decisions of that body, it is neither to be expected nor wished that the Government should not have some control over its proceedings. The addition of a certain number of non-professional individuals to be appointed by the Government would be one obvious means of meeting the difficulty: another, and, I think, more satisfactory plan, would be to render the sanction of the Secretary of State for the Home Department necessary to all the regulations of the Council which, in the opinion of that officer, concern the interests of the public. To such a constitutional control, for virtually it would be that of Parliament, there could be no reasonable objection.

The duties of a Council thus to be appointed would be to make the necessary arrangements, which should be uniform in the three kingdoms, for examining all persons

desirous of obtaining a license to practise, to determine the extent and mode of education of the student, and to act as a board of health. In any general plan of improvement, it is earnestly to be hoped—that those entrusted with the responsible office of dispensing medicines—the druggists and chemists, namely, should be required to pass an examination touching their knowledge of the properties of drugs, chemistry, and so forth.

The question which has been, and will be, most warmly discussed, is, how far the institution of such a faculty would interfere with the interest of existing institutions. As, according to the plan most generally approved, the body above contemplated would only grant a license to practise, there is every reason to suppose, from past experience, that a large number of the licentiates would still apply to the College of Physicians and Surgeons for their diplomas, and that thus the funds of those institutions would be kept up as far as would be required for all useful purposes: if, however, there should be any deficiency, it might be removed by a grant from the general funds of the faculty. Whatever plan of reform may be adopted, it is earnestly to be hoped that there may be honorary distinctions as a reward for high scientific acquirements. I do not believe that the dissatisfaction which prevails respecting the present inequalities in the profession, relates, generally speaking, to the differences themselves, but to the exclusive and objectionable principle upon which they are made to depend. If the honours of the profession were open to all who chose by their own exertions to obtain them, I do not see on what possible grounds an objection could be raised against them. It would indeed, in my opinion, augur badly for the elevation of the profession, as a learned and scientific body, if all were to be reduced to the level of mediocrity; the great object, on the contrary, should be, by judicious encouragement, to induce as many as possible of the junior members of the profession to take the highest possible degree.

But to render this plan unobjectionable and equitable, it would be quite indispensable that the present corporations should be placed upon a liberal footing, the respective members of each having a control in their government. The institution of a faculty like that contemplated, would, in fact, require such an alteration, as without it there could not be that harmony and mutual confidence which would be so essential to the successful working of the whole scheme.

In devising any new plan for the government of so important and numerous a body as the medical profession, it is clearly impossible to foresee all the results which may flow from such an extensive change, or to say that some existing interests may not be

affected; but the published proceedings and opinions of those who advocate reform, show that there is every desire on their part to preserve, as far as may be feasible, the powers and funds of the various Colleges and Universities. Let us, then, hope, that there may be sufficient public spirit among the existing corporations to induce them to sacrifice, as far as may be necessary, their own peculiar privileges, to the public good, and that we may see all the branches of our common profession continuing to elevate it in dignity, and to extend it in utility. But if this may not be, let all who are sincere in their professions as reformers steadily persevere, in the full conviction that what they seek being in itself both reasonable and just, must ultimately succeed; for, to conclude with the words of one of the most distinguished members of our profession, Sir James Clark, we may confidently affirm that “such a union of the whole profession as is here advocated must come; it is irresistible, because it is the only reform which is consistent with the natural order of things, that is founded on justice, or can place the medical profession, as a body, in the position which it ought to hold among the other liberal professions.”

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

November 8, 1842.

DR. WILLIAMS, THE PRESIDENT,
IN THE CHAIR.

THE first meeting of the season was held on Tuesday evening last, when there was a very full muster of the profession,—indeed, the large library was literally crammed with the Fellows and their friends. During the recess, considerable improvements have taken place in the arrangements of the rooms, which are now much more convenient than formerly, and they really form a very excellent suite, as a door has recently been made from the anteroom into the council chamber, where tea and coffee are served after the meetings; whereby the crowding and inconveniences often felt during last season are now greatly obviated. The portrait presented to the society by the widow of the late Dr. Yelloly, the founder of this learned corporation, has been placed over the president's chair; and it forms not only an elegant but a most appropriate ornament to the library. Altogether, the *locale* of the society has now assumed rather a brilliant appearance.

The only paper read was a

*Case of Paralysis without Loss of Sensation,
from Disease of the Cervical Medulla.*

By JOHN WEBSTER, M.D. &c.

As considerable attention has recently

been directed to affections of the nervous system, especially since the important discoveries of Sir Charles Bell and other physiologists have thrown much light on these intricate questions, any new facts must always possess interest, even if they should not clear up some of the difficulties embarrassing the subject. With the view, therefore, of contributing to this desirable end, the author begged leave to bring before the society the following interesting case of a gentleman who had been his patient for several years:—

W. H. G., Esq., æt. 36. — In 1836, Mr. G. had a phagedenic ulcer of the left leg, which got well after some months; but it again broke out in 1839, when he had also a large chronic ulcer on the posterior pharynx of some duration, but not of a syphilitic character. He had pains in the head, with very costive bowels, during the greater part of the year 1839; in January, 1840, epileptic attacks, with very slow pulse, now supervened; and in the spring following, Mr. G. had spasmodic contractions of the lower limbs, accompanied by a sense of weakness in the back; and latterly he lost the use of his legs, and ultimately the entire control over every muscle situated lower than the neck. During the last twelve months of the patient's life, the whole body was paralysed, excepting the head, neck, and diaphragm, by which breathing was entirely carried on, and not by the muscles of the chest. However, sensation remained perfectly natural throughout the entire surface of the body; and towards the termination of the disease, the patient's feelings were even more acute than usual, and he could always tell, on the slightest touch of a bystander's finger, the exact spot to which it was applied. Severe spasmodic twitchings of the legs and arms were now more frequently noticed than before, and these were sometimes so violent as almost to throw the patient off his couch. The extremities were often very cold, but occasionally they felt also burning hot, with a sensation of excessive coldness in the epigastrium. The urine was drawn off by the catheter for many months, but latterly it passed involuntarily, as the feces did likewise. All the symptoms continued unabated in violence to the last, and the patient died in July 1842, but retaining his intellectual faculties perfect until the last.

Treatment.—Medicine had very little influence in arresting the disease, although the treatment may have relieved the severity of some of the symptoms. The remedies consisted principally of purgatives, mercury, sarsaparilla, hydriodate of potassa, strichnia, and morphia to procure sleep or allay spasm. Other means were also used, but the treatment which

appeared to produce the most benefit was active purging, and the tincture of cantharidis taken as a diuretic; at the same time that a copious discharge was kept up for many months consecutively from two large issues on the nape of the neck.

Autopsy.—Nothing particular was found in the head, excepting that the arachnoid membrane over the pons varolii adhered to the parietal layer of that tissue, and about two ounces of serum were found in the ventricles; but there was no tumor or change of structure either in the brain or in the cerebellum. The thoracic and abdominal viscera were healthy, with the exception of the bladder, which was much contracted in size, thickened in its coats, whilst the omentum, and some of the small intestines, adhered to its surface. On opening the spinal canal, the theca, corresponding to the three or four lower cervical vertebrae, was much distended; the arachnoid cavity was filled with lymph, and there were adhesions of the membranes to the chord, which appeared firmer at the anterior than at the posterior portion, and the parts were inseparable. The chord itself was longer than usual at this particular point, felt soft and pulpy to the touch, and on being divided it was found to be in an almost diffuent state, infiltrated with serum, but of a natural colour. For the extent of half an inch above this point the chord exhibited a dusky red colour, but there was no difference observable betwixt the two columns, both being alike softened and discoloured; the parts above and below being perfectly healthy, and of a natural appearance.

A very interesting discussion ensued upon the reading of the above paper, in which Mr. Shaw, Mr. Arnott, Dr. Williams, Mr. B. Cooper, Mr. Rawlins, Dr. Weatherhead, Mr. Coulson, the author, and some others, joined, but our limited time and space prevent us from giving any report, however much some of the observations made during the evening deserve to be recorded.

UNIVERSITY OF LONDON.

BACHELOR OF MEDICINE.—SECOND EXAMINATION, 1842.

Nov. 7.—Morning, 10 to 1.

Physiology.

Examiner, Professor T. RYMER JONES.

1. Describe the mechanical, chemical, and vital properties of Muscular Fibre.

2. What are the propelling agents employed in effecting the circulation of the blood during its passage through the venous system?

3. Describe the circulatory and respiratory organs of a Crustacean (*e. g. Lobster*), and of an insect; and point out the principal differences between them.

4. Describe the structure of the stomach of a ruminant quadruped and the process of rumination.

5. Describe the minute structure of the liver of a mammiferous animal, and the nature of the biliary secretion.

6. Describe the structure of the compound eye of an insect.

Nov. 7.—Afternoon, 3 to 6.

General Pathology. General Therapeutics and Hygiene.

Examiners, Dr. BILLING and Dr. TWEEDIE.

1. Describe the local phenomena of inflammation, or the changes which take place in an inflamed part. Give an outline of the essential nature of inflammation.

2. State the indications to be kept in view in the treatment of dropsy.

3. Describe the specific effects of the emanations arising from stagnant water on the human body; and mention the measures best calculated to counteract their pernicious influence.

4. Translate the following passage into English:—

At vomitus, ut in secundâ quoque valetudine sæpè necessarius biliosis est, sic etiam in his morbis, quos bilis concitavit. Ergo omnibus, qui ante febres horrore et tremore vexantur; omnibus, qui cholera laborant; omnibus etiam cum quâdam hilaritate insanientibus; et comitiali quoque morbo oppressis, necessarius est. Sed si acutus morbus est, sicut in cholera; si febris est, ut inter horrores, asperioribus medicamentis opus non est; sicut in dejectionibus quoque suprâ dictum est: satisque est, ea vomitus causâ sumi, quæ sanis quoque sumenda esse proposui. At ubi longi valentesque morbi sine febre sunt, ut comitiales, ut insania, veratro quoque albo utendum est. Id neque hieme neque æstate rectè datur; optimè, verè; tolerabiliter, autumno. Quisquid daturus erit, id agere antè debet, ut accepturi corpus humidius sit. Illud scire oportet, omne ejusmodi medicamentum, quod potui datur, non semper ægris prodesse, semper sanis nocere.—*Celsus*, lib. ii. cap. xiii.

Tuesday, November 8.—Morning 10 to 1.

Surgery.

Examiners, Mr. BACOT and Sir STEPHEN HAMMICK.

1. How would you dress, place in position, and subsequently treat, an extensively incised wound of the integuments and muscles, on the anterior middle third of the thigh? How does such treatment differ from

that you would pursue in a lacerated, in a contused, in a deep-punctured bayonet-wound of the same part? Give your reasons for the management of each respectively.

2. What are the symptoms and appearances in an acute inflammation of the Integuments of the lower extremity which would induce you to think that it would either terminate in resolution, in suppuration, in ulceration, or in mortification? State the foundation for such opinion.

3. Describe the various dislocations of the Elbow-joint, how they are detected, the appearances of the limb, and the mode of reduction.

4. In an amputation of the Leg, supposing you had the choice of the whole space between the knee and ankle-joints, whereabouts would you begin your incision? Give your reasons for such preference: then detail the instruments and dressing you are likely to require, describing every step of your operation; the position of yourself and patient whether it be a right or a left limb; the stoppage of the circulation, whether by tourniquet or otherwise; the incisions; the mode of using a retractor; the sawing of the bones; the securing the arteries, whether by tenaculum or forceps; or if you should require the needle, how it is to be used; the restraining bloody oozing from the cut surface in debilitated constitutions; the dressing of the stump; position in bed; time of renewal of the dressings; the removal of ligatures; and subsequent management of the patient.

Nov. 8.—Afternoon, 3 to 6.

Medicine.

Examiners, Dr. BILLING and Dr. TWEEDIE.

1. Describe the symptoms, anatomical characters, and treatment, of acute hydrocephalus.

2. Enumerate the principal varieties observed in the expectoration in pulmonary diseases, and the diagnostic inferences to be drawn from each.

3. Detail the principles of treatment in infantile convulsions.

4. State the characteristic appearances and varieties of Rupia.

5. Explain how Pneumo-thorax may arise. Give its physical signs. How is it to be treated?

6. Describe the symptoms and morbid appearances in dysentery. Give an outline of the treatment.

November 9.—Morning, 10 to 1.

Midwifery.

Examiner, Dr. RIGBY.

1. Enumerate the changes in the female breast which are produced by pregnancy.

2. Enumerate the different varieties of extra-uterine pregnancy; their duration and probable mode of termination.

3. At what period of pregnancy is premature expulsion of the fetus least dangerous, and at what period is it most so? Explain the reason why.

4. Enumerate the injurious effects which may result from hurrying the expulsion of the child.

5. Enumerate the indications for applying the forceps and for turning.

6. Define the operation of artificial premature labour, and describe the mode of inducing it as recommended by modern authors.

7. What are the injurious effects as regards the mother and child in allowing difficult labour, from contracted pelvis, to go on too long without assistance?

8. What is the diagnosis between prolapsus and polypos uteri?

November 9.—Afternoon, 3 to 6.

Forensic Medicine.

Examiners, Prof. DANIELL, Dr. PEREIRA, and Dr. RIGBY.

1. What are the advantages of Marsh's process for the detection of arsenic? and what are the sources of error to be guarded against?

2. How would you proceed to test for corrosive sublimate in the contents of a stomach, in a case of suspected poisoning?

3. What are the symptoms and most appropriate treatment of poisoning by oxalic acid? What is the average period of death after the ingestion of large doses of this poison? Describe the post-mortem appearances, and state how you would detect the presence of the poison in the contents of the stomach, after the appropriate antidote had been administered.

4. What are the symptoms and appropriate treatment of poisoning by *Aconitum Napellus*?

5. In the unimpregnated and in the pregnant state, what are the proofs of pregnancy having previously existed?

6. What are the appearances which indicate recent delivery, as shown during life and after death?

the kingdom. Besides giving the number of deaths (and the causes of them), registered during the 13 weeks previous to the 30th of September, it also gives the average of deaths in the same quarter of the four preceding years, and so shows the general and local increase or decrease in the mortality.

The total number of deaths registered during the quarter for those 114 principal districts (there are 447 registrars for all the country) is 39,069, out of a population of 6,534,535. Exclusive of the metropolis, the number of deaths is 28,950, out of a population of 4,663,808.

The number registered in the metropolis during the quarter was 11,019, out of a population (June, 1841) of 1,870,727.

As compared with the average number of deaths in the same quarter of the four preceding years, 1838, 1839, 1840, and 1841, there is an increase in the past quarter of no fewer than 2,474 deaths, the average for those four years having been 36,595, while the deaths in the past quarter have been, as above stated, 39,069. This includes the metropolis, where, however, there were two deaths in the past quarter less than the average of the four preceding years; so that the increase of 2,474 deaths is to be accounted for in the country. The increase of population, however, has to be taken into account, as reducing the proportionate increase of deaths. The population increases in the town districts about 174 annually, which would reduce the average of deaths applicable to the summer of 1842 from 39,069 to 38,208, or 861 deaths less than those actually recorded. Still, this would leave an increase of deaths upon the quarter of no less than 1,613.

The deaths registered for the 114 districts in the first quarter of the present year amounted to 44,479. In the second (or spring) quarter they were 38,190. Thus there were 879 more deaths in what is called the summer quarter (ending September 30) than there were in the spring quarter.

The mortality was 2 per cent. greater than the summer average, which is at the rate of 23 deaths annually in a population of 1,000. In the last summer quarter, ending September the 30th, the mortality was at the rate of 23.4 annually in 1,000—namely, 23.0 in the metropolitan districts, and 23.6 in the provincial towns.

The following are some of the towns in which the most remarkable increase of deaths has taken place:—In Brighton 310, or 70 above the average (240) of four former years; Plymouth 343, or 178 upon 165; Redruth 288, or 77 upon 201; Penzance 283, or 84 upon 199; Clifton 426, or 115 upon 311; Cheltenham 259, or 79 upon 180; Liverpool 1,956, or 158 upon 1,798; Tynemouth 360, or 80 upon 280. The

MORTALITY IN ENGLAND AND WALES.

THE quarterly table of the mortality in 114 of the principal districts of England and Wales has just been published. It embraces nearly all the large towns as well as the more rural districts, and therefore affords a fair criterion of the rate of mortality throughout

undermentioned towns in the manufacturing districts present the following results:—In Kidderminster the number of deaths in the last quarter was 172, an increase of 63 upon 109, the average of former years: Dudley 568, or 147 upon 421; Walsall 243, or 91 upon 152; Wolverhampton 508, or 87 upon 421; Nottingham 429, or 79 upon 350; Preston 482, or 73 upon 409; Chorlton 679, or 214 upon 465; Manchester 1,614, or 191 upon 1,423; Bradford 820, or 115 upon 705; Leeds, 1,133, or 114 upon 1,019. At Rochdale, Sheffield, Huddersfield, Merthyr Tydvil, Newtown, and Wrexham, the deaths were much under the average of the four preceding years.

The registrars almost universally attribute the increase of deaths to the prevalence of scarlatina and bowel complaints, in which they include diarrhoea and cholera. The children have been the chief sufferers. In St. Anne's, Nottingham, out of the 133 deaths registered, 52 were of children under one year of age. At Chorlton 28 children died of diarrhoea, of whom 23 were children of the working classes. It is amongst the working classes, the registrar says, that the disease has been most fatal. The increased mortality at Brighton has been chiefly amongst young children.

In the metropolis, as has been said, the deaths from all causes exhibit a decrease of 2 on the average of former years. The decrease of deaths from epidemic, endemic, and contagious disorders, has been 251. Deaths from small-pox exhibit a decrease of 251; from typhus, of 153. On the other hand, there is an increase of 260 from diarrhoea (total from this disease 477), and from cholera of 74. In other respects, the return from the metropolis presents no striking features.—*Times*.

LAWS RELATIVE TO INSANITY IN FRANCE.

By the act of 30th June, 1838, each department is obliged to provide a public establishment, especially destined for the reception and treatment of lunatic patients belonging to the district; or to arrange, under the sanction of the Minister of the Interior, with a public or private asylum in the same or a neighbouring department, to receive their insane paupers; and it is permitted, in certain cases, to appropriate a separate division, in civil hospitals, for lunatics, provided there is sufficient accommodation for not less than fifty patients. As every lunatic establishment is placed under the direction of the Préfet of the department, the President of the Tribunal, the King's Procureur, the Judge of the Peace, and the

Mayor of the Commune, and as they must be visited by the King's Procureur of the Arrondissement at least every six months (in addition to the visits made by the Préfet, and the other official persons delegated by him, or the Minister of the Interior, for that purpose), there is some guarantee that they will be properly conducted; but besides these regulations, before an establishment can be opened for the admission of insane patients, all rules for their internal administration must be approved by the minister before they can be put in force. By another clause of the same act, it is expressly forbidden for any person to establish, or even to superintend a private insane asylum, without the authorization of Government; and in such cases it is also enacted, that every house, intended for the reception of lunatic patients, must be entirely separate from any private establishment receiving inmates affected with other diseases; and the King's Procureur of the Arrondissement must visit all the private asylums in the district, at least once every three months, at undetermined periods. According to the King's ordonnance of the 18th December, 1839, which regulates many details not comprehended in the previous Act of 1838, it is ordered that each public asylum for the insane shall be administered under the authority of the Minister of the Interior, and the Préfet of the department; assisted by a commission of five members, acting gratuitously, and appointed by the Préfet. The director of the establishment, and the physicians, both chief and assistants, are, in the first instance, nominated by the Minister; but if vacancies afterwards occur, the Minister must appoint from a list of three candidates proposed by the Préfet. However, the patronage still remains, in reality, with the Minister, as he may add certain parties, of his own free will, to the list of candidates, and then nominate the favoured protégé to the vacant office. Besides, as the Minister may revoke the appointments of director and Physicians, upon the report of the Préfet, as he alone settles the amount of the salaries of these officers, and farther, as the Préfets are the servants of the Minister, by whom they are appointed, and at whose pleasure they retain their offices, the Minister of the Interior is, in fact, the sole patron and dispenser of all the important appointments now attached to the public insane asylums in France; much in the same way as the Minister of Justice has the patronage of those in the law. Although the chief physician must reside, according to this ordonnance, within the asylum, he may nevertheless, by favour, obtain a special permission from the Minister, if he chooses, to live elsewhere; but in that case he must visit the lunatics confided to his care at least once every day, and in

case he is prevented doing so, this duty must be performed by a resident physician.

Such are some of the general regulations respecting public insane asylums; but when any person is desirous of obtaining a license to open a private establishment, the applicant must petition the Préfet of the department in which the proposed asylum is to be situated, to whose satisfaction he must prove, that he is twenty-one years of age, and in the enjoyment of all his civil rights; that his conduct and morals have been good during the three previous years, as shown by the certificate of the Mayor of the Commune in which he has resided; and lastly, that he is a Doctor of Medicine. But in cases where the petitioner does not possess this last qualification, he may produce an obligation from some physician, who must engage, with the Préfet's approval, or undertake the medical duties of, and to reside in, the asylum; and as the Préfet can, at any time, revoke this appointment, it is not likely the treatment of the patients will be much neglected. Further details respecting the constitution and the ordinary government of public and private insane establishments in France, might be given; but as enough has already been said regarding the general administration of these institutions, I will only add, that besides the official persons previously mentioned, there is also an Inspector General of all the lunatic asylums of the kingdom, whose special duties, amongst others, are to visit and report upon these establishments to the Minister of the Interior; and as that responsible office is now ably filled by my old friend M. Ferrus, formerly physician to Bicêtre, and well known to the medical profession by his works on insanity, it is superfluous to speak of that gentleman's qualifications for such an appointment.—*Dr. Webster's Pamphlet on Insanity, 3d edit.*

NEW METHOD OF PREPARING SPIRITUS ETHERIS NITRICI

ADAPTED FOR MANUFACTURERS.

BY DR. GEISELER.

LET 24 ounces of rectified spirits of wine, sp. gr. 0.840, be mixed with 4 ounces of concentrated sulphuric acid, sp. gr. 1.845; allow it to stand for eight days, and then pour the mixture on 4½ ounces of perfectly dry saltpetre, previously introduced into a distilling vessel; adapt the head and receiver thereto, and draw over with a moderate fire 20 ounces of the liquid, which may be rectified with magnesia. Prepared in this manner, a copper still with a tin head and refrigerator may be employed. Another advantage is, that the ethereal product thus obtained is not very subject to decomposi-

tion. A mixture of pure nitric ether and spirits of wine will not furnish an officinal *spiritus etheris nitrici*, since this latter contains, in addition to the components of the former, aldehyd. It cannot be preserved over magnesia or bicarbonate of potassa (see *Phar. Trans.* p. 354), since these additions induce decomposition and formation of nitrate of the alkali.—*Annals of Chymistry and Practical Pharmacy.*

OFFICINAL IODIDE OF POTASSIUM

USUALLY contains, according to Woehler, iodate of potassa and carbonate of potassa, more especially that iodide which is furnished by manufacturers on the large scale. Herzog has shewn the composition of that prepared according to the *Pharm. Borr.* The salt of the *Pharm. Hanov.* frequently contains also iodate of potassa, since it is only completely reduced by the long-continued action of sulphuretted hydrogen. The best method is by decomposing the iodide of iron with carbonate of potassa at a boiling temperature. The difficulty is, to hit the precise point of decomposition, so that neither iodide of iron nor carbonate of potassa may remain in excess. The latter fault is easily amended by the addition of hydriodic acid.—*Annals of Chymistry and Practical Pharmacy.*

POISONING BY SNAILS.

A FAMILY of peasants living in the commune of Clermont, near Toulouse, fell a sacrifice to poisoning by snails. The physician who attended them communicated the following details to the *Journal de Toulouse*.

From what I collected concerning the circumstance which preceded the disease, and those which accompanied it, and from the symptoms which I myself witnessed, I had no difficulty in recognising a case of poisoning like those occasioned by narcotico-acrid vegetables, such as belladonna, hyoscyamus, thorn-apple, &c. No doubt remained in my mind as to the cause of this terrible disease, as soon as I knew that the snails eaten had been collected in the bushes called in French *redout*, but in the patois of the country *ronduit* (*Coriaria myrtifolia*). Every one knows that the leaves and young shoots are a poison to the domestic animals which browse on them, and that they kill them, after causing giddiness, and a kind of epileptic attack; but a fact which is not known, is, that the flesh of these animals may occasion the greatest danger, and even death itself. Symptoms like those which I have just witnessed are rare; but it is common to see among our peasants indisposition caused by snails, which comes from their eating

them as soon as their gathered. The example of the ancient Romans should be followed, and these animals should not be brought to table until they have been kept six months or a year, feeding them on bran and wild thyme. This is the way also to make them fatter and more savoury.—*Gazette Médicale*, Oct. 22, 1842.

TAR IN SKIN DISEASES.

DR. CLESS, in referring to a case of psoriasis treated by Dr. Blich, the cure of which he ascribes solely to the use of tar ointment, takes the opportunity of directing attention to the great efficacy of tar in all kinds of chronic disease of the skin. Following Emery's example, he has used it with success, for the last three years, in a great number of cases, in the Catharine Hospital, at Stuttgart.—*Haeser's Repert.*; and *Schmidt's Jahrb.*

OBSERVATIONS

ON SOME OF THE

SIGNS OF LIVE AND STILL BIRTH,

IN THEIR APPLICATIONS TO MEDICAL JURISPRUDENCE.

BY DR. BECK.

In all cases of alleged child murder, one of the great questions to be established is the fact of the child having respired or not. As the signs by which this is to be determined are still the subject of much difference of opinion among medical jurists, it becomes important to enlarge our existing stock of knowledge, by the accumulation of new and repeated observations. With this view, I have embraced every opportunity that has been thrown in my way of examining the dead new-born subject. The following observations are founded upon the examination of ten such subjects, which I have been enabled to make through the kindness of some of my professional friends. To Dr. Wilson, formerly physician of the Bellevue Hospital, from which institution many of the subjects were furnished, I am particularly indebted. As the circumstances connected with the birth of each are known, no doubt or uncertainty can attach to the accuracy of the conclusions drawn from them.

Among the tests principally relied on to determine this question, the most important are the following. 1. The static test. 2. The hydrostatic test. 3. The state of the ductus arteriosus.

1. THE STATIC TEST. This test is founded on the fact, that the act of respiration causes an increase in the weight of the lungs. There are two forms in which this test has been applied. The first is by comparing the

weight of the lungs with that of the body. This is commonly called Ploucquet's test. The second is that of taking the absolute weight of the lungs.

a. *Ploucquet's test.* This is so called from its having been originally suggested by Ploucquet. It is founded on the fact, that as soon as respiration takes place in the new-born infant, an additional quantity of blood penetrates the lungs, in consequence of which these organs become heavier than anterior to respiration. As the weight of the body of the child cannot undergo any change, he suggested accordingly, that a comparison of the weight of the body of the child with the weight of its lungs, would furnish a test by which to determine whether it had respired or not. From the few observations which he made, he came to the conclusion that where respiration had not taken place, the proportion between the weight of the lungs and that of the body was as 1 to 70; while on the other hand, where respiration had taken place, it was as 1 to 35; or in other words, that the weight of the lungs was doubled in consequence of respiration. A test so beautiful as this, and founded apparently upon principles so truly physiological, it was hoped would aid, very materially, to solve this important question. Numerous experiments and observations were accordingly made to test its accuracy in actual practice; and the result has been, that while some appreciate it very highly, by others it is viewed as altogether uncertain. In the ten cases which I have examined, the proportions are the following:

Children that had respired.	Children that had not respired.
1. 1 : 43	1. 1 : 58
2. 1 : 35	2. 1 : 36
3. 1 : 44	3. 1 : 49
	4. 1 : 32
Average, 1 : 40	5. 1 : 50
	6. 1 : 52
	7. 1 : 54

Average, 1 : 47

Now the conclusions to be drawn from these observations are manifestly adverse to the accuracy of this test. Taking the individual cases, there is not a single one of those which had not respired, which reach the proportions laid down by Ploucquet, while in the same list, cases 2 and 4 are very nearly the proportions laid down for children that have respired. If we take the general averages, too, of the cases, we find that they do not correspond with the proportion suggested by Ploucquet.

Since the time of Ploucquet, a great number of observations have been made by other persons, and as the result, they have all fixed upon different proportions. The following are some of them.

Before respiration.	After respiration.
Schmitt . 1 : 52	1 : 35
Chaussier . 1 : 49	1 : 39
Devergie . 1 : 60	1 : 45

These, as being deduced from a large number of cases, come nearer the true proportions than those of Plouquet, and correspond more nearly with my own observations. Still, however, it is to be recollected that they are mere average numbers, and therefore do not meet the circumstances of individual cases, which of course they ought to do, for the purpose of rendering them practically available. It may be asked, then, is this test to be rejected altogether? As an infallible one, it certainly should be. Notwithstanding this, it is still, I think, valuable as furnishing corroborative proof, and should, therefore, never be neglected. It should always be taken with other signs; and when this is done, it may aid very materially in coming to a correct conclusion.

b. Absolute weight of the lungs. By some it has been supposed that the actual weight of the lungs would furnish another criterion of the fact of respiration having taken place or not. Accordingly an average weight of 1000 grains has been proposed for the lungs of a child which has respired, and 600 grains for those of a child which has not respired. A moment's reflection, however, must convince us that this is still more uncertain than the test of Plouquet. Children, born at the full time, we know, differ greatly in their weight, and of course there must be a corresponding difference in the weight of the lungs. I have known a child born at the full time, healthy and perfect in every respect, and yet weigh only four pounds; while children weighing eight, nine, and ten pounds, are by no means uncommon. The lungs, therefore, of a child which had not respired, of nine pounds, would probably weigh more than those of a child of four pounds, which had respired; and such has been found to be the case by actual observation. In the cases which I have examined, the following were the weights.

Before respiration.	After respiration.
1. . . . 540 grs.	1. . . . 396 grs.
2. . . . 720	2. . . . 800
3. . . . 900	3. . . . 814
4. . . . 890	
5. . . . 900	Average 670
6. . . . 690	
7. . . . 689	

Average, 761

An analysis of these weights will show at once how fallacious this test must be. We have here, in three cases, before respiration took place, the lungs weighing more than those which had respired; while the general

average weight is greater in those which had not respired—just the reverse of what it ought to be, according to this test.

[To be continued.]

ON THE
LOCAL TREATMENT OF CHANCRES,
BY
SULPHATE OF COPPER AND CYANURET
OF MERCURY.

By DR. STROHL.

THE more rapidly primary syphilis is cured, the less likely are secondary symptoms to appear. The first object is most easily attained by cauterizing. Sometimes, however, this method is inapplicable; for instance, when the sore is very extensive, or much inflamed. In such cases, the author employs the sulphate of copper. The sores are dressed five or six times a day with charpie, which has been soaked in a solution of about a grain and a half of sulphate of copper to an ounce of water. Simple chancres, when thus treated, usually heal within twelve days. Dr. Strohl assures us, that he cures complicated chancres in an equally short time with an ointment composed of two grains of cyanuret of mercury to an ounce of axunge. This ointment is spread upon a piece of linen corresponding to the size of the sore. This dressing is apt to be painful at first; and it must occasionally be taken off, after it has been on for an hour or two, and the remedy must be applied in a weaker form. The pain is said to be most violent in half an hour or an hour, and frequently ceases entirely in two or three hours. When the chancre is extensive and painful, after the ointment has been on from four to ten hours, according to the sensibility of the patient, it is dressed with mercurial ointment, or opium cerate.

If the edges of the chancre have flattened, if the centre is cleaner, the pain less, and the suppuration healthy, (which may occur after the first application of the cyanuret of mercury, but, at any rate, not later than the fourth), the treatment with the sulphate of copper is finished.—*Oesterr. med. Wochenschrift, and Schmidt's Jahrb.*

SUCCESSFUL TREATMENT OF
IDIOCY.

M. SEGUIN, a young philanthropist, who has devoted himself to the instruction of children afflicted with idiocy, proposed to teach after his method a number of children taken from the hospitals. The *Conseil des Hospices*, on the report of M. Orfila, granted his

request. He was entrusted with twelve children, from the age of eight to sixteen, who were living in the Hospital of Incurables, and who were certified to be idiots of reputed incurability. Not one of them could read or write; several could but stammer a few words; others merely uttered a few inarticulate sounds; some were epileptic, and three or four had continual convulsive movements. After a year of assiduity, M. Seguin presented the children to a commission composed of MM. Fouché, Halpher, and Orfila. It was found that they could all read, and that some could write copies; that almost all spoke distinctly, and that their answers were correct; some could add, subtract, and even multiply.

They had also gained much physically, so that those children who before were merely a burden to the house, are now of use to it.

The Council, considering these results, has decided that M. Seguin, who previously was merely authorised to make trials, should have an express commission to continue them on a greater scale, and should be lodged, boarded, and paid by the administration. A special credit will be asked for this purpose from the Council-General of the department. We do not doubt but that the Council will join in so interesting a work.—*Gazette Médicale*, Oct. 22, 1842.

[In Dr. Aikin's amusing story, "The Boy without a Genius," a child, whose dulness has defied all former instructors, is successfully taught by a very patient schoolmaster. M. Seguin's success is another lesson of the same kind, and shows what patience can effect when rendered inexhaustible by benevolence.—*Translator's Note*.]

ADDENBROOKE'S HOSPITAL, CAMBRIDGE.

WE have to announce the election of three surgeons to this hospital—Mr. Lestourgeon, Mr. Hammond, and Mr. G. M. Humphry. "The latter (says the Provincial Medical Journal) was, we believe, comparatively a stranger, but the circumstances of his election are highly honourable to him: he was a distinguished pupil of St. Bartholomew's School, and obtained the Gold Medal on the examination for the Bachelor's Degree in Medicine at the University of London. The announcement of the vacancies at Addenbrooke's Hospital induced him to proceed to Cambridge, where he was honourably elected, in consequence of the character obtained by his successful studies." We are happy to add our testimony to that of our contemporary; Mr. Humphry having been known to us for a considerable time as a very useful contributor to the pages of this journal.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE VI.

*On the State of the Uterus in the First
Month after Conception.*

ANATOMISTS have enjoyed few opportunities of examining the contents of the human gravid uterus soon after conception. Though Dr. W. Hunter was nearly forty years in London, he states that "the most early case of pregnancy which he ever had an opportunity of examining in the dead body, was of three complete months."

Mr. Ogle has given an account, in the second volume of the Transactions of a Society for the Improvement of Medical and Chirurgical Knowledge, of the appearances which Mr. J. Hunter saw in the examination of a young woman who poisoned herself when the period of conception, he believed, could not exceed a month; and probably was much within that time. The arteries of the uterus were injected, and the smaller vessels filled to so great a degree of minuteness that the whole surface became extremely red. The cervix uteri and os tincæ were of their natural size; but the body, or that portion of the uterus next the fundus, was a little enlarged, and more prominent externally in the middle. The spermatic vessels were also enlarged. On cutting into the substance of the uterus, it had more of a laminated structure than in the unim-

pregnated state. This appearance of lamellæ was seen, upon examination, to be formed by veins somewhat enlarged, compressed, and transversely divided. The uterus was unusually soft in texture, and terminated on the internal surface in a pulpy substance. The blood-vessels of the uterus passed into and ramified upon this pulpy substance, which was continued across at the cervix uteri, so as to make the cavity of the uterus a circumscribed bag: and at this part the pulpy substance was so thin as to resemble the retina. This cavity had a smooth but irregular internal surface, and the pulpy substance upon which it was formed was evidently coagulated blood, and varied in its thickness in different parts. Upon a longitudinal section of the uterus, the posterior part of the coagulum, which was the thickest, was nearly half an inch: where it terminated towards the cervix, it was pendulous and unattached. There were also several loose processes, all turned towards the cervix; one of them very thin, as broad as a silver penny, and only attached by one edge to the fundus near the opening of the right fallopian tube. On slitting open the fallopian tubes, the coagulum was found to pass some way into them, and to extend more than half an inch on the left side, which had the corpus luteum. The coagulum was thickest at the orifice of the tube, and there adhered to the inner surface for the eighth part of an inch; beyond which it became smaller, and terminated in a point. In the left tube the coagulum was in two places coiled or folded upon itself, as if thrown back by the action of the tube. The portions of the coagulum at the orifices of the tubes were hollow. When the inner surface of the cavity of the uterus was examined with a magnifying glass, it was found extremely vascular, and dotted with innumerable whitish spots too small to be seen with the naked eye. The uterus was opened in a basin of clear water. The

incision was conducted with great circumspection, and very slowly continued, till the whole of its cavity was exposed. Every part of the internal surface was minutely examined with magnifying glasses; but in no situation was there any thing resembling an embryo to be found.

It has been inferred from this dissection that certain changes always take place in the uterus previous to the reception of the ovum, and that the embryo does not acquire a visible form for some time after these changes have been made.

As the ovum was not discovered in the tube, no conclusion whatever can be drawn from this dissection respecting the condition of the uterus, before the ovum enters its cavity. The ovum, indeed, might have entered, and also made its exit from the cavity of the uterus before the woman died, or before those changes in the uterus, above described, took place; but the probability is, that, though not detected, the ovum actually was in the uterus.

Sir E. Home has given the following description of the uterus and ovaria of a young woman, who died, as he supposed, eight days after conception, and which has often been referred to by authors:—The right ovarium had a small torn orifice upon the most prominent part of its external surface, which led to a cavity filled up with coagulated blood, and surrounded by a yellowish organized structure. The os uteri was completely closed with a firm gelatinous matter, and the two orifices at the superior angles of the uterus, by which this viscus communicates with the fallopian tubes, were open. The inner surface of the uterus was covered with coagulable lymph, among the fibres of which, near the cervix, was the ovum. It was oval shaped, and though at first partly transparent, became opaque from the action of the spirit. It was immediately taken to Mr. Bauer, who compared it to the egg of an insect, and succeeded in pointing out the effects of impregnation in two projecting points, the rudiments of the heart and brain.

It is impossible to admit that the rudiments of the heart and brain of the embryo could have been developed at this time, and been seen, without the amnion, chorion, vesicula umbilicalis, and the different parts of an organized deciduous membrane; and had these existed they could not have escaped some notice. I have no doubt that the right ovarium contained a false corpus luteum; and that the appearances here so generally and vaguely described in the uterus were not the result of conception. Sir E. Home attempted, from this case, to revive an erroneous opinion of Malpighi, viz. that the corpus luteum is not the effect

of impregnation, but a glandular structure in which the ovum is formed.

Dr. Burns states that he has examined very carefully three uteri within the first month, and was not able to discover either ovum or foetus.

Mr. Alexander Shaw has furnished me with the following description of three specimens of the uterine organs after recent impregnation, which were in the collection of Sir Charles Bell. In all of these the orifices of the fallopian tubes were visible at each angle of the fundus, or presented the same appearances which they exhibit in the unimpregnated condition of the organ. The woman from whom the first preparation was taken, had her leg crushed by the wheel of a waggon. The limb was amputated on the fourteenth day after the accident. She had informed the nurse that she was in the sixth week of pregnancy. The uterus was nearly twice as large as it is in the unimpregnated state; and this organ, together with the ovaria, the fallopian tubes, and the alæ vesperitilionis, were in a remarkable manner loaded with blood. The left ovarium had a more turgid appearance than the right: it contained a corpus luteum, and a bristle could be passed through the rent in the peritoneal covering at this part. The walls of the uterus were three quarters of an inch in thickness; there was an accumulation of mucus in the cervix and os tincæ, and the glandulæ Nabothi were enlarged. An extremely vascular deciduous membrane lined the uterus. Its surface was villous and smooth in all its extent; it was confined to the body of the uterus. The uterus was dissected so as to expose the orifice of the left fallopian tube—that is, on the same side on which the corpus luteum was discovered. When the angle at which the tube enters was laid open, a distinct channel was seen formed in the deciduous membrane, and leading to the point where its opening is naturally found. This passage, and the opening into the tube, was free; so that a bristle could be introduced into the orifice, and met with no obstruction until it was fully inserted within the walls of the uterus. The ovum was not discovered.

The young woman from whom the next specimen was obtained poisoned herself. The uterus was increased in size, and its fundus uteri was turgid with blood. A deciduous membrane was seen occupying the body of the uterus. There was a firm plug of mucus contained in the cervix and os tincæ. The orifices of the tubes were visible at each angle of the fundus, or presented the same appearances which they exhibit in the unimpregnated state. A bristle could be introduced into them; but, as in the former preparation, owing to the narrowness of the

canal, there was an obstruction when it arrived at the part where the tube is enclosed within the parietes. The corpus luteum was in the right ovary. The ovum was not detected.

The third specimen was removed from the body of a young woman who poisoned herself with sulphuric acid. The uterus was larger and softer than in the unimpregnated state. On slitting it open a gelatinous deposit was found in the cervix, and a deciduous membrane occupied the proper cavity. Adhering to the fleecy decidua, Sir Charles Bell found a small body, which he imagined might be the ovum. The orifices of the fallopian tubes, as they enter the cavity of the uterus, presented the same appearances which have been described in the two preceding preparations. The right ovarium contained the corpus luteum.

Baer examined the inner membrane of the uterus soon after supposed conception; and he says the villi were elongated, and between these, and passing over them, was an organized substance, evidently the deciduous membrane. The vessels of the uterus were continued into this substance, and formed a number of little hoops around the villi, and anastomosed with each other. The ovum was not discovered either in the uterus or tube.

E. Weber, in 1830, examined the uterus of a woman who committed suicide on the seventh or eighth day after impregnation was supposed to have taken place. The uterus, tubes, and ovaria, were enlarged and congested. One of the Graafian vesicles was burst, and a layer like organizable lymph, composed of little cylinders, covered and intervened between the enlarged villi of the internal membrane of the uterus. The ovum was not detected either in the uterus or tube. "These observations of Baer and Weber are those, (says Professor Wagner,) that treat of the decidua at the earliest period of its existence, even before the entrance of the ovum into the uterus."

It is a remarkable circumstance, that in none of the preceding histories of the human uterus, soon after actual or supposed impregnation, was the ovum seen either in the tubes or in the uterus, and they furnish, therefore, no information respecting the state of the uterus before the entrance of the ovum. These dissections prove that all the blood-vessels of the uterus enlarge, and the different coats soften and are more easily separated soon after conception; that the inner surface becomes covered with a soft substance like coagulable lymph, or deciduous membrane; and that the cervix is closed by a viscid gelatinous matter formed by the glands situated in it. They further demonstrate, that the fallopian tubes are open, and that these canals communicate with the

cavity of the uterus, as they do before impregnation. The ovum, therefore, at first, must lie loose in the cavity of the uterus, like the ova of the lower animals, and have the power to attach itself to any point of the internal surface of the organ, and even to the circumference of the cervix.

In every case, observes Dr. Burns, the decidua, consisting of two layers, is completely formed before the ovum descends. When the embryo passes down through the tube, it is stopped when it reaches the uterus by the inner layer which goes across the aperture of the tube, and thus would be prevented from falling into the cavity of the uterus, even were it quite loose and unattached. By the growth of the embryo, and the enlargement of the membranes, this layer is distended, and made to encroach upon the cavity of the uterus, or, more correctly speaking, it grows with the ovum. This distension or growth gradually increases until at last the whole of the cavity of the uterus is filled up, and the protruded portion of the inner layer of the decidua comes in contact with that portion of the uterus itself which remains attached to the outer layer. Breschet, Velpeau, and almost all the numerous recent writers on embryology, have repeated this statement.

Researches in regard to the state of the mucous membrane of the uterus after conception, says Wagner (1841), inform us that even before the arrival of the ovum within its cavity an exudation of an albuminous fluid takes place from its surface, which, soon acquiring consistency and the appearance of concrete fibrine, is gradually formed into a membrane, thin and delicate at first, but which continually increases in thickness, and finally presents a fac-simile or mould of the inner cavity of the uterus. This membrane even appears though the ovum never reaches the cavity of the uterus, but passes through the various stages of its evolution in the ovary, fallopian tube, or abdomen.

I believe this is the doctrine now taught in almost all the anatomical schools in this country and on the continent, although it is unsupported by a single observation; and is proved to be erroneous by all these dissections. There is no case, as far as I know, of early gestation, in which the fallopian tubes have been seen covered with decidua before the arrival of the ovum in the uterus, and you will soon be convinced that the decidua reflexa cannot be formed in the way this hypothesis supposes. This hypothesis, in fact, rests entirely upon certain appearances observed within the uterus in some cases of extra-uterine gestation, from which no inferences can be drawn which are applicable to ordinary pregnancy.

Dr. W. Hunter examined a case of fallopian tube gestation in which the uterus was enlarged, and the membrana decidua was distinctly seen lining the fundus uteri. From this appearance he inferred, that the decidua, or outer stratum of the secundines, belongs to the uterus, and not to the ovary, or that part of the conception which is brought from the ovum.

Although it be extremely probable, says Dr. Baillie, that the decidua begins to be formed at the time that the ovum passes into the cavity of the uterus, yet it is not absolutely necessary for the formation of the decidua that the ovum should reach that cavity. When an ovum grows in the ovarium or the fallopian tube, the decidua is both formed in the uterus, and the uterus is considerably enlarged, so as to undergo, to a certain degree, changes exactly similar to those which take place in natural pregnancy.

Though the fœtus be extra-uterine, observes Dr. Denman, the uterus becomes considerably enlarged, and performs its proper office by providing the efflorescent or deciduous membrane for the reception of the ovum.

Dr. Burns says, it is curious to observe that invariably the uterus enlarges considerably, and "in every instance decidua is formed." Meckel, Breschet, Velpeau, and every other author with whose writings I am acquainted, have given the same opinion on this subject; and not only has this been considered an undoubted fact in all cases of extra-uterine gestation, but in common pregnancy it has been supposed that a deciduous membrane is invariably formed within the uterus, before the ovum enters its cavity. That the decidua is not formed within the uterus in all, or in any cases of extra-uterine gestation, the following facts seem to prove.

A lady died suddenly in 1829, from internal hæmorrhage, produced by rupture of the right fallopian tube, which contained an ovum. On opening the tube, and examining the different parts of the ovum, I found a deciduous membrane every where surrounding the chorion, and closely adhering to the inner surface of the tube, as the decidua usually does to the lining membrane of the uterus, in ordinary gestation. Within the decidua, the chorion, placenta, amnion, and embryo, were distinctly seen. The uterus was larger than natural, and there was not the slightest trace of any decidua lining its internal membrane. Had it existed, or any thing resembling a layer of coagulable lymph, it could not possibly have avoided detection. The lining membrane is now in precisely the same state it then was, and by examining the preparation [exhibiting it], you will see that there is a decidua surrounding the ovum in the tube, but not a vestige of decidua within the uterus. Dr. Merriman was present

at the examination of the body of the lady from whom this specimen was obtained; and it led me first to doubt the correctness of Dr. Burns's statement, that in every instance decidua is formed in the uterus. I soon after this found that in a case recorded by Mr. Langstaff in the *Medico-Chirurgical Transactions*, and in another by Velpeau, there was no deciduous membrane found within the uterus.

On the 18th of July, 1836, a patient of Dr. Stodart's, after suffering for some time with symptoms of inflammation and retroversion of the uterus, was seized with great faintness and soon expired. A large quantity of fluid blood was found in the abdominal cavity, and the right fallopian tube, which contained an ovum of ten or twelve weeks, was extensively lacerated near the fimbriated extremity. On removing the uterus and its appendages from the body, and carefully examining the ovum contained in the right fallopian tube, it was evident that a deciduous membrane every where surrounded the chorion, and adhered to the inner surface of the tube. The placenta which was situated at the extremity of the ovum nearest the uterus, was seen covered with the decidua, and coagula of the fibrine of the blood, were traced from the interstices of the placenta through the decidua into veins, in the thickened muscular coat of the tube. The cells of the chorion were full of coagula of fibrine. Between the chorion and amnion, near the placenta, was seen the vesicula umbilicalis, with its slender peduncle proceeding to the umbilical cord. The appearance of the amnion, cord, and embryo, was perfectly natural. The uterus was considerably enlarged, and its inner surface was coated with a very thick layer of a yellowish-white soft substance, like common adipose matter, or lard, and bearing not the most distant resemblance to deciduous membrane. There was no trace of any vessel in this thick coating. The orifice and neck of the uterus were closed with the usual viscid substance formed by the Nabothian glands. The appearances are well preserved in the preparation of the parts [exhibiting it]. You observe there is a perfect ovum within the tube, and that the vesicula umbilicalis floats about in the spirit when it is moved. M. Velpeau, I think, states that he has a preparation in which this is present; but I have never seen one, except this, in which the vesicula umbilicalis was in the tube. The soft thick substance lining the uterus, is, you see, entirely different from the deciduous membrane of this ovum [exhibiting it], which was expelled in abortion at the end of the second month of pregnancy.

But these are not the only cases of extra-uterine gestation, in which there was no decidua within the uterus. Dr. Blundell states that he

"has seen two tubal cases in which the decidua was wanting;" Dr. Murphy has described a case in the *Dublin Journal*, for 1838, in which there was no decidua within the uterus. It was not ascertained whether in these cases there was a decidua in the tube, but there can be no doubt of the fact, for the decidua is as essential to the embryo in the early months of pregnancy, as the placenta is to the fetus in advanced gestation. In a case which occurred to M. Chaussier in 1814, the decidua surrounded the ovum in the tube. Mr. Streeter has pointed out to me a case of extra-uterine gestation, (tubal) the history of which has been recorded by Dr. Cookworthy, in the 1st vol. of Dr. Johnson's *Medico-Chirurgical Journal*, in which "there was no *membrana decidua*" within the uterus. Mr. O. Clayton has related in the *Lancet*, very recently, another instance of tubal gestation, in which there was no true decidua in the uterus, but a membrane which had a considerable resemblance to it at first sight, and might have been mistaken for decidua, as many membranes have been which have been expelled from the uterus during painful menstruation.

From these facts we may conclude, that the decidua is not invariably, if ever formed within the uterus in cases of extra-uterine gestation, and that if it were so, further evidence would still be required to prove that an organised membrane always lines the uterus, like a shut sac, before the ovum enters its cavity after common impregnation.

Two diagrams, from Baer and Purkinje, are here subjoined, to illustrate the description of the Graafian vesicle and human ovum, given in Lecture III. p. 96.

FIG. 1.

Fig. 1 is a diagram of a section of the Graafian vesicle and its contents, shewing the situation of the ovum. *a.* The granularly membrane. *b.* The proligerous disc. *c.* Ovum. *d.* The inner and outer walls of the Graafian vesicle. *e.* Indusium of the ovary derived from the peritoneum, the stroma immediately underneath which is condensed so as to form the *tunica albuginea*.

FIG. 2.

Fig. 2 is a diagram representing a section of the hen's egg within the capsule of the ovary, and the position of the vesicle of Purkinje. *a.* The granularly membrane, forming the periphery of the yolk. *b.* The vesicle of Purkinje embedded in the cumulus. *c.* The vitellary membrane. *d.* The inner and outer layers of the capsule of the ovum. *e.* The indusium of the ovary. Between the indusium and the capsule the stroma is seated. *f.* The pedicle by which the capsule is attached to the ovary.

CLINICAL LECTURES,

Delivered at St. Thomas's Hospital,

BY SAMUEL SOLLY, Esq., F.R.S.

Assistant-Surgeon, and Lecturer on Clinical Surgery, at St. Thomas's School.

On Diseases of the Spine.

I HAVE selected the diseases of the spinal column as the first subject for consideration in the lectures on clinical surgery, which this season it will be my duty to deliver. It is one to which your attention will be frequently called in private practice, and one which is much neglected by the student during his attendance at the hospital.

There is no portion of the human frame which is more interesting, in a physiological point of view, than the spinal column; and our knowledge of physiology will assist us more in the treatment of its diseases than similar knowledge in regard perhaps to any other part of the body.

I have often had occasion in this theatre to dwell upon the important part which the muscles perform as accessory and intelligent ligaments—binding bones together, strengthening joints, and affording especial support when and where it is most required. Illustrating my observations by the structure of the knee-joint, the principal strength of which is to be sought, not in the ligaments, strong and numerous as they are, but in the powerful extensor and flexor muscles which surround it with their aponeurotic tendons, and brace it up on every side. This principle may be well applied to the organization

of the spine in connection with the diseases to which it is liable. The student who neglects to include the muscles of the back in his consideration of the mechanism of the spine as a series of joints, studying only the ligaments, will never be able to reason correctly upon the causes which produce spinal distortion, or employ judicious means for its correction. In the chamber of the sick, you must not regard the spine simply as an inflexible column from which the muscles moving the upper extremities may act as from a fixed point. If you were to take the pains to watch the varied movements of this beautiful column when exposed;—an opportunity which, unfortunately for anatomists as well as for artists and sculptors, is seldom afforded in this inclement clime,—you would see how flexible it is, and how much it is influenced by the muscles attached to it. Every school-boy knows how fatiguing it is to sit for any length of time on a form without a back to it; but have you, since you have been studying anatomy, ever reflected that such fatigue demonstrates how much more the vertebral column must be supported by muscular fibres, which experience fatigue, than by ligamentous fibres, which do not? Ignorance of the general physiology of muscular action, and the particular physiology of the dorso-spinal muscles, first opened the door to the quack and instrument-maker to undertake the treatment of spinal deformity instead of the surgeon: and I can conceive no greater amount of horrible torture inflicted on the human race, than that which ignorant and unprincipled men have perpetrated under the plea of curing deformities of the spine: it has cast a stain upon the profession, for ignorance of physiology and anatomy has not been limited to quacks and mechanists.

The study of the muscles of the back is looked upon by the pupil in the dissecting-room as a mere exercise of the memory, which is necessary for him when he is going up to the College, but of no value whatever in the practice of surgery. Often and often have I been asked by students what is the use of learning the muscles of the back, for we shall be sure to forget them as soon as we have passed the College? Nor is it of any use if they merely learn their origin, and insertion, and relative position, without understanding philosophically their actions and offices. The best method of studying the anatomy of these muscles, so as to retain a knowledge of their functions which will avail you in the treatment of the deformities of the spine, is to include all the muscles attached to the spine, inclusive of the sacrum,—not merely the muscles of the back—in one list, and then to arrange them under four heads:—1st, Those which arise from the spine, and are inserted into the extremities;

2d, those which arise from the spine, and are inserted into the ribs; 3d, those which arise from the spine, and are inserted into the head; 4th, those which arise from one portion of the spine, and are inserted into another.

In the first division you have on each side seven—the *latissimus dorsi*, *trapezius*, *rhomboidei*, *levator scapulæ*, the *psosæ*, and *quadratus lumborum*.

In the second six, and one set—the *serratus posticus*, superior and inferior *sacro lumbalis*, *levator costarum*, *scaleni*, and *diaphragm*.

3d, Ten—*splenius capitis*, *complexus*, *trachelo mastoideus*, *obliquus superior capitis*, *rectus posticus major* and *minor*, *rectus lateralis*, *rectus anticus major* and *minor*.

4th, Ten, and three sets—*longissimus dorsi*, *sacro-lumbalis*, *spinalis dorsi*, *semi-spinalis dorsi*, and *colli*, *cervicalis descendens*, *transversalis colli*, *splenius colli*, *obliquus inferior capitis* and *longus colli*, *multifidus spinæ*, *inter-spinales*, and *inter-transversales*.

The term origin of a muscle is very apt to mislead the student, as it conveys the idea that it is invariably the fixed point, instead of being in its turn moveable, as is the case with regard to almost all the muscles of the body, and especially so in the muscles of the back. For instance, the *latissimus dorsi* muscle is described as arising from the ilium, the sacral and the lumbar vertebrae, and the ribs, and inserted into the humerus. When these points which are called the origin are fixed, its action is to move the upper extremity backwards, and rotate it inwards. But suppose its insertion to be fixed on one side, the right arm, for instance, while the muscles attached to the spine on the left side remain in a relaxed state, then will the *latissimus dorsi* muscle act from the arm as the fixed point, and curve the lower portion of the spine to that side, and draw up the right hip. The action of both muscles from the arm upon the trunk is well seen if we lay hold of a bar above us, and draw the body up to it, when the arms are of course the fixed points, and the spine the moveable one. From this illustration you will comprehend how all the muscles between the extremities and the spine are to be considered in connection with distorted spine: acting both from the spine on the arms and legs, and from the arms and legs on the spine. Also that, in order to move the arm on one side, the spine must be first fixed by muscles attached to the opposite side; just as the muscles which act from the *os hyoides* upon the lower jaw to open the mouth can only produce that effect while the *os hyoides* is fixed by those muscles which connect that bone to the sternum and scapula; for when it is not so fixed, the

very same muscles raise the os hyoides as in the act of deglutition. And although the spine is not so moveable as the os hyoides, still the ligaments alone are not sufficient to prevent its being drawn out of the perpendicular line.

In connection with the attachment and action of the spinal muscles, the surgical pathologist must study well the direction of the articulating surfaces of the vertebræ, in order to connect in his mind the influence which these muscles have over the joints of the spine. He observes in the cervical region that the articulating surfaces are nearly horizontal; consequently that this portion of the column must be dependent for its erect position upon the ligaments which run from one bone to the other, and to the numerous muscles which are attached to it; for he sees that there are no projecting lips of bone on the sides of the articulating surfaces whereby they are locked together, as is the case in some joints, and in portions of the spine in many of the lower animals. As this mode of articulating the bones gives great freedom of motion, it necessitates a greater number of muscles to keep it upright. In the dorsal region, as the articulating surfaces are placed nearly perpendicularly, the spine does not require the same amount of force to prevent it falling forwards as to prevent it inclining to one side, and he meets with that enormous mass of muscles usually described as the longissimus dorsi, sacro-lumbalis, spinalis dorsi, semi-spinalis dorsi—muscles known in the aggregate as the erector spinæ muscles.

In the lumbar region he sees that the great breadth of the bones, and the corresponding great extent of intervertebral ligaments, with the locking together of the bones, limits the motion, and renders necessary the fewer muscles to move and to support it.

In these observations on the physiology of the muscles of the back, you will perceive that I have only attempted to shew you the importance of the subject in relation to spinal diseases, without entering minutely into all those details which it is capable of, both in an anatomical and physiological point of view.

Deformities of the spine may be divided into two grand classes: first, those which result from disease commencing in the osseous tissue, and those which are occasioned primarily by a want of sufficient support from the muscles which are attached to the spine. This deficiency on the part of the muscles may arise from general debility, from partial debility,—the muscles on one side obtaining the mastery over their antagonist muscles on the opposite side; from excess of power in the muscles of one side,

in consequence of their being more constantly employed than their antagonists, which remain comparatively idle, and from a variety of other circumstances which shall be referred to hereafter. The deformity which is consequent upon diseased bones is an angular curvature, the convexity projecting backwards. Its diagnosis is extremely important, and it shall form the subject of future observations.

In the other class of distortions, the spine is more or less curved laterally, and known under the name of *lateral curvature*. And although caries of the spine is occasionally to be met with in connection with lateral curvature, it is not usually the primary affection; and for general purposes the terms *angular* and *lateral* curvature sufficiently distinguish them into two grand pathological classes.

I have now selected the subject of lateral curvature, as it may be well illustrated by the following case, taken when the subject of it was first admitted by Mr. Perry, and subsequently by her present dresser, Mr. Renwick:—

I will now read to you the case. Harriet Town, æt. 18, milliner, single, slight made, and rather stumous appearance, admitted into Lydia's ward, St. Thomas's Hospital, on the 15th of August, 1842, with lateral curvature of the spine. The principal curve in the dorsal region, with its convexity to the right side; slighter curve in the lumbar region; convexity to the left side. The general appearance of the figure not much altered, when viewed anteriorly; but posteriorly, in addition to the deformity produced by the curvature of the spine, the projection of the scapula is very decided. She traces her present condition to ill health six years ago. At this time she suffered much from pain in her left side, which caused her to lean in that direction. There has not been any catamenial disorder. Menstruation came on at the age of fourteen, and continued regularly since that period, though her general health has never been very good.

She says she is at present getting worse, that she is very weak, that her appetite is very variable, that she perspires on the slightest exertion; she complains of dull aching pain in the loins, much increased by percussion on the vertebræ; occasional numbness of the legs, but no paralysis of motion. The treatment pursued before her admission was chiefly the administration of tonic medicines, and the application of strengthening plasters to her back. She attributes the want of improvement to having closely devoted herself to needle-work. On her admission, I directed her to maintain the recumbent posture during the greater part of the day, and to use her left hand and arm in learning to sew, not employing the right

more than was absolutely necessary; a moxa on the side of the lumbar portion of the spine, where her pain was more severe; as a tonic medicine—mist. iodin. c. gent. ter die; pil. aloes c. myrrh, occasionally.

It is now just two months since she was admitted, and she has been very much benefited by the treatment: the curvature is much less; the shoulder-blades do not project so much; she has very little pain in her loins, and her general health is very decidedly improved.

The distortion of the spine in this case arose principally from a want of power in the erector muscles of the spine to perform their office as accessory and intelligent ligaments in maintaining the spine in a straight line when the muscles of the right scapula were unduly called upon; and although we must not altogether omit the fact of her being induced to incline to the left side, in consequence of the pain she experienced, I considered that the action of the trapezius rhomboidei and latissimus dorsi muscles belonging to the right arm, not being, from this general debility, sufficiently counteracted by those of the left, were the principal agent in the production of the deformity. The pain which she suffered in the lumbar portion of the spine indicated the strain upon the ligaments in that situation, occasioned by the yielding of the spine in the formation of the second or supplementary curve to counterbalance the original or dorsal one. The result of the treatment shews that the bodies of the vertebræ had not yet been materially altered in form, as you see in the preparation before me—the result of longstanding disease. In all lateral curvatures of the spine, the intervertebral substance is necessarily compressed on the concave side of the curve; and when such pressure has continued for some time, absorption takes place, which does not stop in the fibrous tissue, but extends to the bone; and in such cases the simple treatment which succeeded in this case would not avail. There is another consequence of the continuance of the deformity unremedied by surgical aid, which this preparation also illustrates;—I allude to the production of this osseous layer, which has been thrown out on the sides of the bodies of the vertebra to act as a natural splint, and strengthen the bent and weakened column. Now, beautifully as this provision exhibits the resources of nature, you will remember that such a growth would render all attempts to correct the deformity not merely nugatory but improper. It is, then, of the greatest importance, in all lateral curvatures of the spine, before you commence your treatment, to ascertain how long the disease has existed, and how far the natural flexibility of the spine is interfered with.

In private practice, when you are called to such a case as the one before us, the probability is, that the friends have no idea that your patient has any affection whatever of the spinal column. They tell you that they wish you to see Miss —, because she has a swelling in her bosom, or that one collar bone is larger than the other, or that her shoulder or her hip is growing out. But as soon as the patient appears, you perceive, from the position of her trunk, the spinal column is in fault.

For, generally speaking, you are called to these cases in quite their early stage, and before the secondary curve, by which the primary one is corrected, has occurred, and the trunk is not carried in the erect posture. There is a halt in her step, arising from the tilt of the pelvis, thus raising one of the lower limbs, and virtually shortening it. You suggest the possibility of the spine being in fault, and request an examination. You next inquire into the history of her ailments; and most probably you find, as in the present case, that there is some defect of constitution, as exhibited in a general want of power, increased by some evil habit arising from improper management during the progress of her education; such as confinement to seats without backs to rest the spine on, or straight high back chairs, which are as bad, or the slavery which many unfortunate females are doomed to undergo, as a milliner's apprentice, with her needle in her hand from morning till night, only interrupted to receive a hurried and scanty meal, which ill provides for the vital wear and tear of so many hours of continued labour.

There are some cases of lateral curvature, but I believe they are very rare, which arise from unnatural action of certain muscles of the spine produced by abnormal innervation—such as we see in infancy, the result of dental irritation, and occasionally followed by various forms of club-foot or partial paralysis. I will call your attention to the first case of this kind, which presents itself in the house. The spine is sometimes bent down in the children of the poor, by its being required to sustain day after day heavier weights than it is calculated to sustain. I saw an interesting case in the summer-time of spinal curvature, in a girl about 14 years old, on the borders of Epping Forest, produced by carrying heavy loads of faggot wood on the right shoulder. Tight lacing is an occasional cause of deformity, though not, as some authors would lead you to believe, the most frequent. The pressure of a very stiff unyielding strap will operate injuriously, by confining the scapula so as to interfere with the healthy and complete action of those spinal muscles which are attached to it. This confinement allows the right arm, which must be used, to obtain

under power. It is also possible that, in weak, sickly girls, the direct pressure of the stays on the ribs may operate upon the spine, driving it from the side on which the pressure is greatest; but such cases are rare.

It is seldom that you find in lateral curvature that the spine is not more or less twisted or contorted. The transverse processes, instead of projecting directly outwards from the spine, are turned together with the bodies, partially forwards and backwards; so that supposing the convexity of the lateral curve is to the right, the right transverse processes project partially backwards; and as they carry the ribs with them, the angles of the ribs project, forming a considerable ridge, throwing the spinous processes further forwards. Mr. Shaw relates a case in which the projection of the transverse processes in the neck was so great that it was mistaken by the practitioner for a tumor, which he attempted to remove by bleeding and blistering.

The contortion or twisting of the spine was, I believe, first described by Dr. Dodds, a surgeon in the navy; and although I cannot agree with him in his explanation of the manner in which such contortion is produced, the fact itself, which is very important, cannot be disputed. The importance of a knowledge of this alteration of the position of the transverse processes is dependent on the effect which it has of destroying the symmetry of the erector spinal muscles on the two sides of the column.

It gives them an unnatural fulness, especially in the loins, which, without due consideration, you might attribute to an inordinate development of muscles, and feel tempted to divide it with your knife, under the idea that such projection of the muscles proved them to be in a state of active contractility.

The muscles of the spine do become shortened on the concave side of the curve; but I agree with Mr. Shaw in considering this as the consequence of the curve, and not the cause of it,—merely an instance of the way in which muscles adapt themselves to alterations in the form of the skeleton.

I must next caution you against confounding simulated disease of the spine with real curvatures. It is not often in private practice that we meet with such deception; though that strange disease, hysteria, sometimes calls forth the powers of its victims to simulate deformity of the spine; but in hospitals and in the army such cases occasionally occur. M. Guerin states that pretended deviations of the spinal column may be distinguished from the morbid by the following marks:—

1. In the simulated deviations, the seat of the deviation is always the same—the

dorso lumbar region; the curve constantly the same, having its centre in the middle of the last dorsal vertebra; absence of a projection or gibbosity in the middle of the convexity of the curve; furrows or folds of the skin, generally two in number, always situated between the crista of the ilium and the last rib; considerable inclination of the trunk, the superior extremity separated very much from the line of gravity; elevation of the hip on the side of the concavity when the heel is detached from the ground; proportional shortening of the corresponding.

2. In the morbid deviations, on the contrary, the variable seat of the curve, the curves multiplied and alternate, one of which is the principal and the other supplementary; constant presence of relief, or dorsal and lumbar gibbosities on the side of the convexity of the curves; cutaneous furrows, pronounced and variable, with regard to the seat, as the deviations themselves; not much inclination of the trunk, on account of the supplementary curves; elevation of the hip almost insensible, or for some time only.

The simple lateral curvature, which the present case illustrates, is consequent on debility of the muscular system, and it must not be confounded with that deformity which is occasioned by imperfect development of the osseous tissue. There is a want of due solidity in the skeleton, occasionally met with in infancy, and known by the name of rickets, which it is necessary we should distinguish from the weakness upon which this lateral curvature depends. The term rickets, or rachitism, has been used so loosely, that it may be well to consider briefly its distinguishing characters upon the skeleton. If you look at this beautiful specimen of the disease, you will see at once that the whole frame-work, from the bones of the feet up to the cranium, is deformed; the bones of the limbs are curved, and more or less twisted on their axis. Their extremities are swollen and deformed; the articulations of the feet and hands offer directions and relations which are not natural; the apophyses and points of attachment of muscles are unnaturally prominent; and, to use the expression of M. Guerin, who has thus described these changes, the ribs are rounded, as it were blown up, and present, at their sternal extremity, a curvature, the concavity of which looks forward and outwards. The chest is thus widened transversely, and depressed into a furrow, in the middle of the articulations of the ribs with the sternal cartilages. The vertebral column deviates laterally or posteriorly, and presents a succession of alternate curves. The surfaces are rounded, and, as it were, distended and swollen, presenting many points of depression, which approach the articulating surfaces of the bodies: the vertebral appendices

participate in the appearances, and are more or less depressed, as it were, *ecrassée*, in the vertical direction, from muscular action. The pelvis has lost its symmetrical conformation. The sacrum is sometimes vertical, and sometimes more curved than natural and thicker than usual. The hip-bones are more or less approached; they are thicker, as are also the blade-bones and sternum; they are shortened and thickened: the head is generally voluminous. The cranium thickened principally on the sides. The bones of the face exhibit, by their exaggerated development, some marked projections, the angles being more acute than natural; the relations of proportions of all the parts of the osseous system are generally perverted. The skeleton in its totality, as in each of the bones composing it, offers a true reduction in length, in extent, and attests an arrest of development. Rickets, properly so called, is a malady of infancy: it is rarely observed in the foetus; more frequently towards the age of 18 to 20 months; very rarely after the age of six years.

Upon 346 cases which M. Guerin examined under this point of view, the invasion took place as follows:—

	Cases.
Before birth	3
During the 1st year . . .	98
2d „	176
3d „	33
4th „	19
5th „	10
From the 6th to the 12th . . .	3
	—
	342

It attacks both sexes nearly equally.
Upon these 346 there were—

Males . . .	142
Females . . .	198
	—
	346

These facts show that many of these deviations of the vertebral column, which have been attributed to rachitism, are produced by other causes. Thus, all the kinds of softening of the bones in adults, and all the deformities which supervene, almost exclusively in young girls towards the age of puberty, are not caused by rachitism.

M. Guerin shews the rachitic softening of the bones as a secondary effect; the disease first exhibiting itself by gastro-intestinal derangements, &c.

The period of incubation, as he calls it, he says is from two to six months. The true characters of the period of incubation are the nocturnal sweats of the belly and head, the tympanitic and swollen belly, diarrhoea without colic, a moist skin, a constant and uniform febrile movement, lastly, great sensibility of the osseous system.

The immediate influence of rachitism

upon the osseous system is shewn by four orders of different facts:—by deformity of the bones; by their reduction in dimension; by the ultimate alterations of their tissue; lastly, by the disturbance and retardation of the progress of ossification.

Rachitic deformity is developed successively from above to below, from the bones of the legs to the femora, from the femora to the pelvis; next, the superior extremities, the thorax; and lastly, the vertebral column and cranium. M. Guerin says, after having opened and examined a great number of rachitic bones, I am convinced that the alterations of texture which they present are positively different, whether they belong to the period of incubation, deformity, or resolution. The diseases with which rachitism has for some time been confounded are, for the most part, deformities of the spine, tubercular affection of the bones, different species of osteo malacia. The deformities of the spine, improperly attributed to rachitism, are all the lateral deviations, of whatsoever nature they may be; excursions, principally tubercular excursions.

Rachitism of the spine does not occur without indications which cannot be mistaken of its existence in other bones. Tubercular excursions are never produced or accompanied by deformities of the lower limbs. Softening of the bones in adults, to which M. Guerin limits the denomination of *osteo malacia*, he considers the results of specific causes—as scorbutus, syphilis, rheumatism, of some particular defect, as the cancerous taint: all those subjects who have shewn it have presented, in the beginning of the softening process, some general symptoms of these alterations. It is announced by vivid and deep pains in the bones. The progress of the disease is slow, and enduring for a number of years, sometimes up to 20. It is not announced simultaneously in all parts of the skeleton, neither below or above, but it only attacks by fractions; so that when we open a subject which has presented it but slightly advanced, we find all the bones separately affected, and at the same time portions of the bones are altogether softened on the one side, and other portions of the same bone preserve their resistance and their normal texture.

M. Guerin states that he possesses many examples of this partial ramollissement in subjects who have died in consequence of cancer of the stomach, breast, or uterus. Osteo malacia and rachitism are thus essentially different. In the one the osseous tissue is merely softened; it preserves none of the consistency or texture of bone; it is as if we poured upon the seat of the softening a very energetic fluid, which had the property of causing all traces of the calcareous salts to disappear, leaving nothing but the fibrous

web, presenting here and there large areola similar to the large venous sinuses of the liver. I have considered this digression necessary, to prevent your confounding the lateral curvature of adult life with that which originates in infancy as the effect of rickets; and I consider no apology necessary for the introduction of the valuable opinions of M. Guerin on this subject.

We must now, gentlemen, consider the treatment of these cases of lateral curvature when they present themselves in the early stages, as in the case which has just been related.

First, then, with regard to the constitutional treatment of such cases. It is a disease of debility, and the constitution must be strengthened; but you must not suppose that this is to be done by simply giving tonic medicines. You must first ascertain the state of the intestinal secretions, not by inquiry, for this is always unsatisfactory, but by the examination of the state of the tongue, and observing the fecal evacuations for yourself, and then giving a purgative, containing a greater or less quantity of mercury, according to their character; for there are none of these cases which do not require some alterative medicine before you can give tonics with benefit. You will select your tonic according to the state of female health, giving a preference to the various forms of steel if the patient has attained the age of puberty, and the menstruation is not regular and healthy. But if, as in the case before us, the functions of the uterus are duly performed, then I think that small doses of iodine with the iodide of potassium, in a bitter mixture, forms an excellent tonic, though it of course requires to be carefully watched, as, after a time, it occasionally disagrees with the stomach, and must be omitted for some other. I have insisted much on the importance of constitutional treatment, but you must not imagine that this can accomplish all: no patient with distortion of the spine will outgrow it without local treatment. If the disposition to curvature is not arrested, instead of outgrowing the disease, the additional length of the spine will only add to the deformity. "A spine, slightly distorted (says Mr. Shaw), in a growing girl, may be made straight; but if it be neglected (however great may be the attention paid to the state of the health), the curve will become decidedly worse; and if it be permitted to increase to such a degree as to render the ribs angular, it is very doubtful whether a perfect restoration of the form can ever be effected." In speaking of local treatment, the time necessarily allotted to a clinical lecture forbids my entering into much detail; but it is very important to dwell upon the principles which should guide your practice;

indeed, it would be impossible to describe all the measures which might be judiciously employed in each peculiar case. Exercise of the spinal muscles, without fatigue, is the first thing to be thought of; secondly, exercise of the spinal muscles, without calling upon the ligament to sustain the spine in the erect posture; thirdly, giving the muscles greater power to maintain their contractile force; fourthly, reduction of inflammation which has been excited in the ligaments of the spine. Thus the recumbent posture is necessary for the ligaments, the maintenance of the erect posture for the exercise of the muscles; and although these two requisites to the cure appear totally opposed, the judicious surgeon will find many ways of effecting the same principle, though his means may vary. Thus, though he must never confine his patient altogether to a sofa, as the total idleness of the muscles would render them wholly useless, he must enjoin the recumbent posture as the rule in the first instance, and the erect posture as the exception. Mr. Shaw has suggested many excellent, and indeed elegant, contrivances for calling forth the energy of the erector muscles of the spine, for the details of which I must refer you to his admirable work on the Spinal Diseases. The practice of rubbing or shampooing the muscles is of the greatest value, as it improves and accelerates the circulation of blood through their vessels. In the case before us I insisted upon her using the needle with her left hand, as she lay in bed, with a view to exercise freely the spino-scapular muscles. As a local antiphlogistic, there is nothing equal to the moxa, the efficacy of which in reducing inflammation has been clearly shown in the present case. In reference to the treatment of more confirmed cases of spinal curvature, all of which require additional mechanical treatment, I must defer my observations to a future lecture.

ILLUSTRATIONS OF THE PATHOLOGY, DIAGNOSIS, & TREAT- MENT OF OPHTHALMIC AF- FECTIONS.

BY EDW. HOCKEN, M.D. M.R.C.S.L. &c.

[Continued from Vol. ii. 1841-2, p. 173.]

A new and improved plan of treating strumous conjunctivitis. The pathology of struma. The nature and symptoms of the local affection, with the rationale of treatment.

STRUMOUS conjunctivitis is a very frequent and distressing disease of the

eye, which occasions severe distress during its continuance, lasts an indefinite period, and is apt to be renewed from slight variations in climate, or any other exciting cause. Those only who have seen much of this disease, the long time it occasionally lasts, the obstinacy it manifests to common remedies, and the great distress and anxiety it occasions both the patients and friends, can appreciate the value of any plan of treatment which promises almost certain and immediate relief, which occasions no pain in its application, nor requires skill or judgment in its use or repetition. Such a plan of treatment I shall have presently to offer to the notice of my professional brethren, and in doing so, I feel persuaded that there are none who will take the trouble to give it a fair trial who will not bear me out in its great superiority, almost unfailing efficacy, and superior advantages.

Strumous disease is not confined to the conjunctiva, but scrofulous inflammations affect the lids, cornea, aqueous membrane, iris, &c.; hence I object to the term of "strumous ophthalmia," which, from the vague meaning of the latter term, might with equal justice be applied to any of these affections as to strumous conjunctivitis. They are all forms of inflammation modified by the condition of the constitution; and before I proceed to describe the local affection, it will be well to consider briefly the nature of the general state of the system.

Struma, in one form or another, is the most prevalent affection which affects the inhabitants of damp and variable climates. Like many other constitutional diseases, the peculiar form possessed by the parent is almost sure to be handed down to the offspring, or a state of system extremely prone to take on similar diseased actions. This fact, among others, proves that several allied, but more or less dissimilar conditions of constitution, are included under the term struma; for, in fact, a merely predisposed condition of system is, in common parlance, termed a scrofulous constitution—such, for instance, as the fine skin, clear delicate complexion, light hair, large blue eyes, long eyelashes, and precocious intellect, of one form; the dry, harsh skin, lymphatic temperament, soft flaccid condition of the muscles, dulness and

apathy of the mind and body of another; or the foul, dry, swarthy coloured skin, swollen countenance, dark hair, &c. of a third. A true condition of constitutional struma, however, depends, not on any mere physical condition of the body, but on actual contamination of the blood by imperfectly assimilated matter, and this state of the blood is itself dependent upon, and kept up by, a peculiar derangement of the digestive and assimilative organs. Both these pathological elements are concerned in the production of strumous conjunctivitis; the fifth nerve suffers from the propagation of irritation from the ganglionic system of nerves—being referred to its extremity—and the inflammation of the conjunctiva is modified by the strumous condition of the blood.

As I have before stated, so now I repeat, that the manifestations of this constitutional disease are different in different grades of individuals. Tubercular phthisis is thus handed down in a peculiar form of the general cachexia, and this cachexia is generated by adverse fortuitous circumstances, manifesting itself in this and other fragments of a great constitutional disease. But the other and more generally recognized indications of struma are rarely present in the phthisical constitution (such as enlarged glands, upper lip, eruptions, &c.) although the pathology is similar, and the products of diseased action identical. Again, where the lymphatic glands undergo strumous deposition and inflammation, the ears are sore, and the skin is affected with eruptions, then it is that the lids and eyes are subject to attacks of inflammation, &c., of which strumous conjunctivitis forms one of the list.

The reason why particular organs and tissues are, as it were, selected by a disease having so wide a diffusion as the mass of circulating blood, is dependent on an attraction which subsists between such parts and the peccant materials contained in the blood. Not only are these matters attracted by the affected tissues, but sufficiently so to separate them from the blood, and to retain and fix them in connexion with the tissues—subsequent processes ridding the system of their presence altogether. From the abundance of the material, and the constancy with which it is renewed, we can readily understand how so many organs are involved, in

severe cases. In all diseases depending upon a specific virus circulating with the blood, I believe that the local disease is set up by the mutual and elective attraction between the tissue and the poison, the ultimate aim being to eliminate it from the system by subsequent processes. This, for instance, is the case in constitutional syphilis, where the discharges attending its local manifestations are themselves poisoned, although the poison is diluted and less virulent than the discharge of primary sores. Dr. Budd, of Bristol, in his very able and interesting paper* on the Symmetry of Disease, has clearly proved that the essential condition of each individual lesion is dependent on detention of morbid matters, and their being held in union or affinity with the part affected.

All the best modern writers have acknowledged the invariable presence of that condition of the digestive organs which I have stated to be the *origo et fons mali*—the source of that contamination of the blood from whence the local phenomena spring. Dr. Todd† states, that in his opinion (in which Sir James Clark concurs) strumous dyspepsia presented a more characteristic feature of this habit of body than any physiognomical portrait which has yet been drawn of it. For upon whatever temperament the diseased constitution called scrofula engrafts itself, this form of dyspepsia will also there be found; and, therefore, being constantly present with it, preceding and accompanying the various symptoms which issue from it, it would be contrary to all reason to refuse it an important share (nay, the whole share, with the other organs of assimilation) in the development of this disordered habit, and in the production of the local affections which have hitherto too much engrossed the attention, to the exclusion of a proper consideration of the constitutional disease.

The derangement in the abdominal and assimilative organs presents some slight diversity of symptoms in different cases. The abdomen is unnaturally protuberant, and entozoa are very apt to generate in some part of the intestinal canal. The tongue is frequently red at the tip and edges, and the papillæ prominent, whilst the centre is

covered with a slimy greyish mucous coat. At other times the whole tongue is covered with a thin opaque mucous covering, through which the papillæ project; or this is distributed in more or less circular confluent spots, often with a brownish dry streak down the centre in the morning. The appetite for food and drink is very uncertain: the patient is often thirsty, and has a ravenous desire for food. Sometimes, on the contrary, there is great loss of appetite, and unaccountable dislikes and fancies. The bowels are generally confined, alternated with occasional attacks of diarrhœa, depending, probably, on the irritation which accumulated matters in the large intestines ultimately set up. The evacuations are unnatural in smell, colour, and consistence; they have a putrid odour, are of a lightish brown colour, a clayish consistence, mixed with much mucus, undigested or partly digested food, and sometimes blood. There is often pain in the stomach or abdomen. The breath is foul, and there is generally much irritation about the nose, mouth, and sometimes the rectum, so that the child picks and scratches these parts continually, and often occasions unpleasant sores. The urine is pale and abundant, depositing the triple phosphates on cooling. The skin is either harsh, dry, and subject to eruptions, or of a fair waxy appearance, with conspicuous veins; in which latter case there is almost always a slight degree of hectic present, and copious partial night sweats. The sleep is seldom perfectly calm and undisturbed; it is either broken suddenly with a start, or the patient is restless, grinds his teeth, talks, or even screams. The throat is apt to suffer in some cases in an advanced stage, from repeated inflammations, and the tonsils undergo chronic enlargement, and in these also the upper lip enlarges, and the membrane of the nose is almost always engaged. The temper becomes irritable and fretful, and the child cries from slight causes—the superaddition of strumous conjunctivitis greatly augmenting this morbid trait.

Although this is but an imperfect sketch of the pathology of struma, it must suffice for my present purpose, and I will now pass on to consider the phenomena of strumous conjunctivitis, omitting strumous corneitis, &c.

* Med. Chir. Trans. Vol. xxv.

† Cyc. of Prac. Med. Vol. ii., p. 654.

What I have endeavoured to establish in the foregoing remarks may be expressed under the following propositions:—That a physical conformation of body, predisposed to struma, does not necessarily imply a strumous constitution: That a peculiar derangement of the digestive, excretive, and assimilative organs is the first source of the disordered habit: That the pathological element of the constitutional disease consists in a contamination of the general mass of the blood with imperfectly assimilated or tuberculous matter: That local diseases arise from an elective attraction between this matter and the tissues, its separation from the blood, and subsequent processes to eliminate it from the system: That there are distinct varieties of constitutional and local manifestations derived from one source: That strumous conjunctivitis is dependent on a propagated irritation manifested in the fifth nerve, and slight inflammation of the conjunctiva.

Strumous diseases of the eye are rare after puberty, and although I have seen strumous keratitis in a man of 23 years, I have never met with the conjunctival disease before two years, nor after puberty. The disease is sometimes severe and of short duration, especially the first attacks, but after several renewals it is apt to linger in a very chronic form, with frequent augmentations from every exposure to change of weather, or increased derangement of the digestive organs.

Symptoms.—On seeing a child with strumous conjunctivitis, the great intolerance of light, and the firm spasmodic closure of the lids, (photophobia and blepharospasmus) especially attract our attention. The orbicularis palpebrarum keeps up a constant pressure on, and irritation of, the affected membrane, by the severe spasm they constantly suffer when exposed even to moderate light: even the mere action of the light on the lids, and of the small quantity which passes through to the conjunctiva, is unbearable, so that the child leans its face on its nurse's shoulder, or if in bed on the pillow, even in comparative darkness. In chronic cases the edges of the lids are kept in this manner in an almost inverted condition, and the eyelashes get under them, and are thus retained, greatly augmenting the distress. Towards

night there is a remission of these symptoms, and in the darkness the child opens its eyes, and appears altogether much better. I believe that the affection is greatly increased, and maintained almost entirely, by this constant source of irritation, (the spasm of the orbicularis), and that to remove the irritability of the lids and conjunctiva is to cure the disease.

When we come to examine the eye, even in children who strive to assist the practitioner, the greatest difficulty is experienced, and in some cases actual force is absolutely required to separate the lids; a proceeding not calculated to improve the features of the case. The necessary exposure to light occasions a profuse discharge of scalding tears, and, on attempting to raise the lid, it often becomes inverted, whilst the eyeball is rotated out of sight upwards and outwards. If we succeed in fairly viewing the eye, we observe a bundle of vessels forming a cone, with the apex towards the cornea; generally very slight, and frequently terminating in a minute translucent elevation, which is an imperfect vesicle or phlyctenula. There may be several of these in different periods of their progress: some incomplete, others collapsed, and forming a minute depression or dimple; some in a state of ulceration, either slight or severe; and others again having cicatrized, and left a small opaque speck or diminutive albugo. They are situated most commonly at the junction of the cornea and sclerotica, sometimes further in on the cornea, and less frequently on the conjunctiva beyond the cornea. Although slight vascularity is a feature of the less chronic cases, and is beautifully seen when the lids can be quickly separated, as in the sleeping child, or seizing an opportunity when the patient is unprepared, yet if much violence has been resorted to, the eye appears much laden with blood, and the lids very vascular.

The affection commences with vascularity of the lids and great intolerance of light; sometimes much watering of the eye. As the case proceeds, sometimes in a few hours, the local symptoms I have mentioned become developed:—The tears are poured out profusely on exposure to the light, the child cries and complains of pain, and frequently sneezes violently, from the propagation of irritation to the nose

from the branches of the fifth nerve supplying the lids and conjunctiva to the naso-labular branch, which passes into the nose through the cribriform plate of the ethmoid. When phlyctenulæ are present they terminate either in a small transparent depression, termed a dimple, or go on to ulceration of various degrees and severity. These ulcers are generally transparent, and not very deep, but in unfavourable cases, and if not attended to, they will sometimes become funnel-shaped, and penetrate deeply, so as to allow the capsule of the aqueous humour to protrude in the form of a transparent vesicle. The base of the ulcer is placed superficially, diminishing in size as it penetrates the different layers of the cornea. If the destructive process be not now checked the aqueous capsule bursts, the aqueous humour escapes, and frequently a portion of the iris protrudes from the wound, forming what is termed myocephalon, from its resemblance to the head of a fly. The cornea is rendered opaque from the cicatrization, forming small specks where the damage has been slight, denser and larger forms of albugo when more severe, and when the ulcer has penetrated and the iris protruded, an indelible opacity, with a central black speck, or a limited staphyloma from the pseudo-cornea, adherent to the iris, being thrust forwards whilst soft by the aqueous fluid. Strumous opacities of these kinds (excepting the latter), will generally lessen or disappear, after a longer or shorter period, by the natural powers being quickened by an appropriate treatment.

As the attacks multiply, and assume more and more of a chronic form, the child acquires a peculiar physiognomy; the brow is contracted, the cheek, ala of the nose, and angle of the mouth, are drawn up, to protect it in some measure from the light; and from the frequent application of the stimulating tears to the cheek, &c., and the susceptibility of the little patient to take on diseased actions, the face becomes excoriated or covered with eruptions. The scalp, behind the ears, and the external ear itself, often suffer from vesicular or pustular disease in this stage. The eyelashes, as I have mentioned, often become inverted under the lid, and the edges of the lids themselves more or less entropic. The eyes and lids are now much more vascular, and the con-

junctival covering of the cornea frequently thickened and vascular, sometimes so much so as to deserve the name of pannus. One or both eyes may suffer either simultaneously or consecutively. One is, in general, more severely affected than the other, or the severity passes alternately from one eye to the other. It is in the chronic stage that the deeper-seated tissues are occasionally involved.

Pathology.—The intolerance of light in this disease is usually attributed to an affection of the retina, but I believe that the true retina has nothing to do with its production: I think, if we examine its symptoms and cure, we cannot fail to trace it to the ophthalmic division of the fifth nerve solely and exclusively. The fifth (this division) is a nerve of sensation, secretion, and nutrition, supplying common sensibility to the eye, and all the contents of the orbit, and overruling the function of the lachrymal gland. If we ask any physiologist how the muscles of the orbit derive their sensibility, he will reply through the fifth nerve, but that the filaments which actually supply these muscles are unknown. Now I believe that the retina itself is in direct communication with the fifth, through the medium of filaments distributed with those of the optic nerve; not, as Magendie thought, the actual nerve of sight, but as the source of common sensibility to light, and the medium of impressions on the iris through the lenticular ganglion. It is true I can offer no actual anatomical demonstration of this opinion, but in this I am not singular, as in the case of the muscles just alluded to; nevertheless I will proceed to show my reasons for thinking so. If a small foreign body, as a grain of sand, get between the upper eyelid and globe, a temporary condition, very analogous to strumous conjunctivitis, is induced: the patient manifests the greatest intolerance to light, the orbicularis palpebrarum is affected spasmodically, *the pupil contracts to a fine point*, and the eye waters profusely. When we come to examine it we find the eye turned greatly upwards, and the same difficulty with the orbicularis. Now, in this case, it is obvious that all the symptoms depend exclusively on an irritation of some filaments of the ophthalmic division of the fifth nerve. But it is equally clear to my mind that although the fifth nerve

private Chinese and Japanese museum; a museum of antiquities (principally Egyptian and Etruscan objects) and a rich well-arranged anatomical and pathological museum, occupying the ground-floor of a neat edifice; the first floor of which contains the library of the university. The university building is a plain structure, surmounted by a dome, containing a saloon, decorated with portraits of former professors, and an examination room. Adjoining is a large and handsome botanical garden, in which are several specimens of rare plants from Java and the Dutch colonies. A separate portion is appropriated to medicinal plants. The number of students at the university amounts to about six hundred, of which one-third attend the medical classes.

The following are the names of the professors of the medical faculty:—Rector, G. Van der Hoeven, who is also professor of comparative anatomy and physiology. Anatomy and physiology, Sandifort. Special therapeutics and pharmacy, Macquelyn. Surgery and obstetrics, Broers. Pathology and practical medicine, C. Pruy Van der Hoeven.

For the first time since I have travelled upon the Continent met here with obstacles to my seeing the hospitals; and the same appeared to have been the case with other medical visitors. Dr. Varrentrapp, of Frankfort, in his "Medical Journey through England, Holland, and Belgium," says "I could not see the town hospital, which also serves as a refuge for the insane.

Physicians are obliged to their assistants to let me see the hospital, and about a week ago, I was in it,

generality of the progress of science in other countries; and the name of any celebrated Dutch scientific or medical character of modern times is rarely heard of in the rest of Europe.

Some opinion may be formed as to matters in Leyden, more especially from the circumstance that, till lately, syphilitic patients were not admitted to be treated in the hospital, as it was considered that the complaint was a just punishment of the sufferer's wickedness. A few, however, of these patients are now received at the clinical hospital.

The *Hague* contains a population of about 40,000 inhabitants, and two hospitals, besides one for the insane. The town hospital is a neat building, with 100 beds, arranged in clean and airy wards of ten or twelve in each, for the reception of medical and surgical diseases. Attached is a garden where convalescents take exercise, and in which was erected, during the prevalence of the cholera, a small building for patients affected by the epidemic, or by contagious diseases. The professional duties are performed by a physician and a surgeon. The other hospital, *Ziekenhuis*, contains about the same number of beds, and is appropriated to the reception of syphilitic diseases, psora, and other chronic cutaneous affections. About three-fourths of the patients are syphilitic: the physician, having also the superintendence of the public women in the town, immediately sends any one who is infected to the hospital. The most usual remedy employed to combat secondary symptoms is the oxymuriate of mercury. In cases of psora, sulphur internally exhibited, and used in the form of ointment, is the usual remedy; tepid baths are likewise a good deal used in this hospital in the treatment of cutaneous diseases. The house for the insane contains about sixty patients, two-thirds of whom are females, and is situated on the first floor, the cells, for the most part, are small, and damp, on the ground floor, and violent patients are confined in their cells, which are guarded by soldiers, and the doors for the patients are most carefully guarded. Most of the patients are

isolated cells for the more refractory. The number of superintendents is only six—four females for the women, and two men for the male patients. The *carnisole* is the usual means of restraint. No special treatment is adopted, nor are the patients engaged in any methodical occupation. There is a small garden attached to the house, in which the more tranquil ones are allowed to take exercise.

The Hague being the seat of government, the organization and interior arrangement of the hospitals, as well as the treatment of disease, are better than in other parts of Holland, with respect to which I am, perhaps, scarcely justified in passing a judgment, from the brief period of my sojourn in the country. But for any one who has been much in the habit of visiting a variety of medical institutions, a long time is not needed to perceive that medicine and surgery are in a very backward state in Holland; and I find this opinion corroborated by Dr. Varrentrapp, who remarks in his work, that although there are doubtless many well-informed, scientific, and even learned men, among the Dutch physicians (of which the rich anatomical and pathological collections, well kept up to the present time in some parts, may be considered a proof) yet that the hospital physicians and practice fell much below his expectations; the visits being made, in some places, by the physician with his hat on, and a cigar in his mouth (this smoking in the wards I did not see, and some of the physicians in the Parisian and other hospitals wear their hats during the visit), which he takes out to ask the patient two or three questions—marking the number of the bed opposite the printed formula in the attendant apothecary's books. Cases are not taken except at the clinical hospitals, and but little interest appears to be taken in the patient in a scientific or other point of view. This indifferent medical organization and practice is

attributed by Dr. Varrentrapp to the absence of there being no efficient authority to superintend the affairs of the medical institutions, as in England, superintendents or inspectors of towns; or

tants, who, for the most part, take but little interest in the control of aught else than the financial matters: to this cause, and to the attachment of the Dutch to old habits, and their dislike to innovation, may, then, be attributed the backwardness of the medical sciences in Holland.

October, 1842.

VESSELS OF THE PLACENTA.

To the Editor of the Medical Gazette.

SIR,

By permitting me, through the medium of your Journal, to make the following statement, you will much oblige
Your obedient servant,

JOHN REID.

Univers. of St. Andrew's,
Nov. 1, 1842.

In a communication "On the Anatomical Relations of the Bloodvessels of the Mother to those of the Fœtus in the Human Species," which I made to the British Scientific Association during its meeting in Glasgow in 1840, and which was afterwards printed in the 146th number of the Edinburgh Medical and Surgical Journal, a remark is contained which I am anxious publicly to correct. It is mentioned in a footnote, in the paper referred to, that I believe that the representation of the manner in which the fœtal placental vessels are distributed, given by Wagner, in his *Icones Physiologicæ*, fascic. i. b. xi. fig. 2, and stated to have been furnished by Weber, is far from being correct." I had lately the satisfaction of visiting Weber, and he not only very kindly shewed me all his preparations, but gave me some portions of his beautifully injected placenta; and from an attentive examination of these, I am now perfectly satisfied that the representation he has given of these vessels is entirely correct. In alling in question the correctness of Weber's representation, I was at the time under the impression, from an examination of the engraving mentioned (which, however, a greater degree of attention paid to fig. 3 might have corrected), that it was meant to imply that the corresponding artery and vein did not run enclosed in the same sheath, but were sometimes coiled about apart from each other; for, being

produces contraction of the pupil *per se*, still under ordinary circumstances the light must fall on the retina to occasion this change. The experiments of Fontana prove that the mere action of light on the iris is insufficient to produce contraction of the pupil, unless the retina be simultaneously affected. But daily observation also proves that if the fifth nerve be in a state of irritation the action of the light on the eyelids alone is amply sufficient to produce the same effects. The experiments of Magendie also tend to confirm the opinion of the function and communication of the fifth nerve, and not, as he imagined, that it was the true nerve of vision; for although the retina was apparently insensible to an intense light from division of this nerve, it does not necessarily follow that the animals were blind. His experiments were performed on rabbits, in whom division of the fifth nerve produces contraction of the pupil; and even here, when he admitted solar light, and concentrated it on the retina by a lens, the animal closed its lids. In some very ingenious and interesting remarks, Mr. Walker* has shown that, under similar circumstances, only sensibility to light is lost, but not the proper functions of the retina. In a patient of his, all the parts supplied by the fifth nerve were paralysed on one side of the face; and in this case there was a striking difference in the sensibility of the two eyes to light. The healthy eye could not bear the same amount of light for a single instant which produced no impression on the eye of the paralytic side: the flame was distinctly visible to the eye, but it produced no irritation. Again, where persons are quite blind, sensibility to light often remains.

Cases of complete amaurosis are occasionally met with where the iris moves with activity and freedom, and where the patients can tell by their sensations the difference between light and darkness, without being able to see at all. These cases appear to dissect, as it were, the different portions of the retina, and show its separate functions—the true retina is paralysed by disease in some part of the visual nervous system, whilst the sensitive function of the fifth, and the motor functions of the third nerves remain intact.

It is clear, therefore, that the intolerance of light, the spasmodic closure of the lids, the profuse lachrymation, the contracted state of the pupil, and the involuntary efforts to exclude the light, in strumous conjunctivitis, are not dependent on any derangement in the state of the retina itself, but on irritation of the various filaments of the fifth nerve which supply these parts, including the retina. And that this is the true pathology of the affection those cases show, where all these symptoms are present without phlyctenulæ or any notable redness; and, moreover, as I shall presently show, that to remove the great susceptibility of this nerve is to cure the disease.

I shall omit the consideration of causes, diagnosis, and prognosis, and pass on to treatment, merely remarking that some accidental increase of the permanent disturbance of the intestinal canal, or the induction of derangement in the eye from common causes—especially atmospheric vicissitudes—excite or establish the ophthalmic affection.

Covent Garden.

[To be continued.]

OBSERVATIONS ON PUS AND MUCUS.

To the Editor of the Medical Gazette.

SIR,

THE insertion of the following observations in your valuable periodical will oblige, sir,

Your obedient servant,

JOHN W. GRIFFITH, M.D.F.L.S.

9, St. John's Square, Nov. 5, 1812.

The mode of distinguishing pus from mucus has occupied the attention of so many authors, and so many pages have been devoted to its consideration, that any further observations at first sight appear unnecessary. In diseases of the chest, now that the physical examination of that cavity by auscultation and percussion renders us so certain of the disease within, assistance is rarely sought for from either the presence or absence of mucus or pus in the expectorated matter. My object here is to notice one or two of the proposed methods of distinguishing one from the other, and

* Philosophy of the Eye, p. 276.

to attempt to show the true relation of pus to mucus. Pus when pure is composed of two kinds of globules floating or suspended in a liquid containing free albumen. The first of these globules are granular on the surface, and much larger than the second, and when acted upon by acetic acid the external part is dissolved, leaving nuclei, varying in number, undissolved; the smaller globules are smooth and transparent, and unaltered by acetic acid. Mucus is composed, as described by Mandl*, of globules undistinguishable from pus, irregularly diffused through a viscid tenacious mass which appears itself composed of numerous very minute granules aggregated into amorphous masses, mixed with some very transparent small globules. The larger globules of mucus seem to me undoubtedly to vary in size according to the density of the medium in which they are contained: thus in the ordinary fluid mucus of the nose they are smaller and appear more granulated, whilst in the urine they are generally larger and less granulated, and of a paler colour, seeming as if distended with fluid. Mixed with the various globules in mucus we have abundance of epithelial scales and cells. The viscosity and tenacity of mucus, varying in intensity from the saline watery mucus secreted in acute bronchitis to the almost solid masses sometimes secreted in the latter stages of phthisis and calculous disease of the bladder, is very characteristic, and is worthy (in a diagnostic point of view) of much more attention than it ordinarily receives. It is never found in pus. The fluid part of mucus does not contain free albumen, but it exists in some unknown combination: its presence has been proved by electricity.† That variety of morbid secretion termed muco-pus is composed of a large number of *pus globules* suspended in a mucous fluid: there is no true pus secreted in these cases, *i. e.* globules and an albuminous vehicle, but the genuine pus globules in the true mucus. The iron, whose presence in pus has been considered as characteristic, exists in the fluid of pus, not in the globules; therefore it is not present in muco pus. I have often been surprised, in examin-

ing the expectorated "purulent" matter in the last stage of phthisis, where there is an enormous progressing ulcerating surface, and when we should expect a large quantity of true pus to be secreted, at not finding more than a trace of free albumen; although the pus globules were abundant. I believe that Gueterbock is perfectly correct in stating* that free albumen is not secreted by mucous surfaces except they be ulcerated; therefore that pus is not secreted unless under the same circumstances. Pus, when contained in urine, falls to the bottom, and forms a bran-like layer, which by stirring is readily diffused throughout the liquid, again subsiding by repose: the urine under these circumstances becomes albuminous. Wherefore, when this sediment is examined by the microscope, the globules are found in great abundance. Mucus by repose falls also to the bottom of the vessel, but by stirring cannot be diffused through the urine like pus, but retains its peculiar viscid gelatinous appearance. When this sediment is examined by the microscope, the globules are few, and separated by the tenacious fluid. The test proposed by Dr. Young to distinguish pus from mucus shews the fallacy of detecting any one constituent of pus. As is well known he proposed producing the coloured rings, by placing the suspected matter between two glass plates, and holding it near the eye, and between it and a candle. These rings are however readily seen in muco pus when the globules only are present. The recognition of pus by the detection of its fatty matter, as proposed by French authors, would also be equally fallacious.

ON

DUTCH MEDICAL INSTITUTIONS.

By EDWIN LEE, Esq.

(For the London Medical Gazette.)

[Continued from p. 146.]

LEYDEN is a handsome town, and, though numbering 40,000 inhabitants, is remarkably quiet. It contains the chief university of Holland, and three or four highly interesting museums, viz. a large museum of natural history; a

* Translated memoir, "On pus and granulation."—L'Experience, vol. 1, 1837.

private Chinese and Japanese museum; a museum of antiquities (principally Egyptian and Etruscan objects); and a rich well-arranged anatomical and pathological museum, occupying the ground-floor of a neat edifice; the first floor of which contains the library of the university. The university building is a plain structure, surmounted by a dome, containing a saloon, decorated with portraits of former professors, and an examination room. Adjoining is a large and handsome botanical garden, in which are several specimens of rare plants from Java and the Dutch colonies. A separate portion is appropriated to medicinal plants. The number of students at the university amounts to about six hundred, of which one-third attend the medical classes.

The following are the names of the professors of the medical faculty:—Rector, G. Van der Hoeven, who is also professor of comparative anatomy and physiology. Anatomy and physiology, Sandifort. Special therapeutics and pharmacy, Macquelyn. Surgery and obstetricity, Broers. Pathology and practical medicine, C. Pruijs Van der Hoeven.

For the first time since I have travelled upon the Continent I met here with obstacles to my seeing the hospitals; and the same appears to have been the case with other medical visitors. Dr. Varrentrapp, of Frankfort, in his "Medical Journey through England, Holland, and Belgium," says, "I could not see the town hospital, which also serves as a receptacle for the insane. The physicians, out of regard to their reputation, would rather not let me see it, for it is truly in a miserable and abominable condition. Not very long ago, the male and female patients lay in it, mixed up together." Although I had made a request the preceding evening, and was at the clinical hospital at the time when the surgeon had finished his lecture—notwithstanding I sent up my name—he declined seeing me, appointing me a late hour in the day at his residence, though I had stated that I was obliged to leave at noon.

The only inference to be drawn from this is, that there must be much to conceal; and, in fact, the medical and surgical practice throughout Holland appears to be in a very backward state. Few foreign medical works are imported; but little is known by the ge-

nerality of the progress of science in other countries; and the name of any celebrated Dutch scientific or medical character of modern times is rarely heard of in the rest of Europe.

Some opinion may be formed as to matters in Leyden, more especially from the circumstance that, till lately, syphilitic patients were not admitted to be treated in the hospital, as it was considered that the complaint was a just punishment of the sufferer's wickedness. A few, however, of these patients are now received at the clinical hospital.

The *Hague* contains a population of about 40,000 inhabitants, and two hospitals, besides one for the insane. The town hospital is a neat building, with 100 beds, arranged in clean and airy wards of ten or twelve in each, for the reception of medical and surgical diseases. Attached is a garden where convalescents take exercise, and in which was erected, during the prevalence of the cholera, a small building for patients affected by the epidemic, or by contagious diseases. The professional duties are performed by a physician and a surgeon. The other hospital, *Ziekenhuis*, contains about the same number of beds, and is appropriated to the reception of syphilitic diseases, psora, and other chronic cutaneous affections. About three-fourths of the patients are syphilitic: the physician, having also the superintendence of the public women in the town, immediately sends any one who is infected to the hospital. The most usual remedy employed to combat secondary symptoms is the oxymuriate of mercury. In cases of psora, sulphur internally exhibited, and used in the form of ointment, is the usual remedy; tepid baths are likewise a good deal used in this hospital in the treatment of cutaneous diseases. The house for the insane contains about sixty patients, nearly two-thirds of whom are females, who are lodged on the first floor, the men occupying cells, for the most part small, badly lighted, and damp, on the ground-floor. The violent patients scarcely ever leave their cells, which are kept shut; an aperture, guarded by a grating, being left in the doors for ventilation. The quieter patients assemble in a refectory at meals. Most of the women sleep in rooms containing four and two beds; there are, however,

isolated cells for the more refractory. The number of superintendents is only six—four females for the women, and two men for the male patients. The *carnisole* is the usual means of restraint. No special treatment is adopted, nor are the patients engaged in any methodical occupation. There is a small garden attached to the house, in which the more tranquil ones are allowed to take exercise.

The Hague being the seat of government, the organization and interior arrangement of the hospitals, as well as the treatment of disease, are better than in other parts of Holland, with respect to which I am, perhaps, scarcely justified in passing a judgment, from the brief period of my sojourn in the country. But for any one who has been much in the habit of visiting a variety of medical institutions, a long time is not needed to perceive that medicine and surgery are in a very backward state in Holland; and I find this opinion corroborated by Dr. Varrentrapp, who remarks in his work, that although there are doubtless many well-informed, scientific, and even learned men, among the Dutch physicians (of which the rich anatomical and pathological collections, well kept up to the present time in some parts, may be considered a proof) yet that the hospital physicians and practice fell much below his expectations; the visits being made, in some places, by the physician with his hat on, and a cigar in his mouth (this smoking in the wards I did not see, and some of the physicians in the Parisian and other hospitals wear their hats during the visit), which he takes out to ask the patient two or three questions—marking the number of the bed opposite the printed formula in the attendant apothecary's books. Cases are not taken except at the clinical hospitals, and but little interest appears to be taken in the patient in a scientific or other point of view. This indifferent medical organization and practice is ascribed by Dr. Varrentrapp to the circumstance of there being no efficient governing body to superintend the administration of the medical institutions, which are either, as in England, supported by private subscriptions or bequests, or else belong to the towns; the direction being confided to six or eight of the more influential inhabi-

tants, who, for the most part, take but little interest in the control of aught else than the financial matters: to this cause, and to the attachment of the Dutch to old habits, and their dislike to innovation, may, then, be attributed the backwardness of the medical sciences in Holland.

October 29, 1842.

VESSELS OF THE PLACENTA.

To the Editor of the Medical Gazette.

SIR,

By permitting me, through the medium of your journal, to make the following statement, you will much oblige

Your obedient servant,

JOHN REID.

University of St. Andrew's,
Nov. 1, 1842.

In a communication "On the Anatomical Relations of the Bloodvessels of the Mother to those of the Fœtus in the Human Species," which I made to the British Scientific Association during its meeting in Glasgow in 1840, and which was afterwards printed in the 146th number of the *Edinburgh Medical and Surgical Journal*, a remark is contained which I am anxious publicly to correct. It is mentioned in a footnote, in the paper referred to, that I believe that the representation of the manner in which the fœtal placental vessels are distributed, given by Wagner, in his *Icones Physiologicæ*, fascic. i. tab. xi. fig. 2, and stated to have been furnished by Weber, is far from being correct." I had lately the satisfaction of visiting Weber, and he not only very kindly shewed me all his preparations, but gave me some portions of his beautifully injected placenta; and from an attentive examination of these, I am now perfectly satisfied that the representation he has given of these vessels is entirely correct. In calling in question the correctness of Weber's representation, I was at the time under the impression, from an examination of the engraving mentioned, (which, however, a greater degree of attention paid to fig. 3 might have corrected), that it was meant to imply that the corresponding artery and vein did not run enclosed in the same sheath, but were sometimes coiled about apart from each other; for, being

taken from a dried preparation, the sheath or villus in which they are enclosed is not represented, and I had not then seen Wagner's *Lehrbuch der Physiologie*, containing a detailed description of these; and it was this supposed error which led me to make the above criticism. If I had supplied, in fig. 2, by the aid of my imagination, the walls of the villus surrounding the convoluted artery, and its accompanying vein, I could not then have questioned its accuracy; for I was maintaining, as the result of my own examinations, that they were enclosed in the same sheath. I make this explanation, not so much from the importance of the subject, for it relates merely to a minor question of anatomical detail, but having, though chiefly from a misapprehension, erroneously called in question the accuracy of an observation made by a most distinguished anatomist and most estimable man, I feel anxious to correct the error.

MEDICAL GAZETTE.

Friday, November 18, 1842.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

ON MEDICAL STATISTICS.

THE taste for statistical information upon various subjects has of late years increased in a remarkable degree. During the present century, this feeling has been gaining ground more rapidly than it ever did before, and a powerful impetus was given to it in 1834 by the formation of the Statistical Society in London, the object of which was to call the attention of the public in general, and the cultivators of science in particular, to the necessity of directing their exertions in this channel. It has enlisted many active and talented labourers, by whose industry much valuable information has been already communicated; and it has also been the means of diffusing abroad more widely the desire

to collect and compare facts in a statistical manner, with the view of deriving more accurate conclusions from them. Since the formation of this society, others of a similar nature, and professing the same object, have arisen in various provincial towns; for instance, one was commenced at Leeds in 1833, another at Glasgow in 1836, besides those which have for some time existed at Manchester, Bristol, &c.

The science of medicine has not been neglected by the members of these societies, many of which have had a separate medical section to suggest and superintend researches in this department, and all have contributed, more or less directly, additions to the stock of our knowledge on medical subjects. In 1833, moreover, a statistical section was formed, in the British Association, expressly for the advancement of medical science.

It may be said of medical science that it is, in a greater degree, perhaps, than any other, dependent for its real advance on the judicious assortment of accurately and extensively collected facts, and of inferences carefully deduced from them. It is in this way alone that we hope to make satisfactory progress, and the want of information of this sort has long been deeply felt by all who are anxious to obtain rational views of diseases and their treatment. Medicine is essentially and peculiarly a science of facts. This is agreed on all hands in its fullest degree: every one thinks so, every one says so, and every one professes to be guided by the sentiment, and to take facts as the basis of his reasoning. But, unfortunately, persons in their eagerness to rest upon facts are not always sufficiently careful in their choice of them. There is something imposing in the term which gives for whatever is so denominated an unreflecting belief. According to the popu-

lar adage, a fact is a stubborn thing—it seems to imply something obvious and tangible, something which cannot mislead, and in opposition to which all reasoning is useless. Such a persuasion would produce a very good effect were all alleged facts truths, but this is confessedly far from being the case, and medical facts have been by no means remarkable for uniformly maintaining this high character. On the contrary, too many can but ill bear an accurate examination. They have been in so many instances too quickly assumed and too readily credited, and are consequently so often falling into disrepute, and giving place to others equally incorrect, that it has been sarcastically remarked nothing can be less deserving of credit than medical theories, except medical facts.

One great cause of this acknowledged imperfection in medical facts is doubtless to be found in the difficulties which beset the subject, arising from the great variety of circumstances to be weighed in the investigation of each disease, as depending on individual constitution, peculiarity of climate, epidemic, &c., and the consequent good judgment and extent of experience which is required to select respectively those circumstances which are essentially connected with the disease, and those which are dependent on the peculiarity by which its course is modified. A correct idea of a disease cannot be formed by taking a narrow view of it, and by seeing it only under certain circumstances, but by observing it extensively in all its different characters. The difficulty of obtaining satisfactory information in this wide field has been so great as to make persons shrink from the attempt, and has unquestionably been the motive for the adoption and long belief in the many so-called facts in medicine, which by further experience and more close in-

vestigation are daily shewn to be erroneous.

But this very difficulty of the subject, this necessity of extending widely the range of observation in order to obtain satisfactory results on each particular branch, calls only for a larger number of labourers, and should act as a stimulus to their exertions. Every accurately-detailed fact, however plain, however devoid of novelty, is in itself valuable: it is something added to the general mass, and plays its part in assisting towards an approximation to the truth, and in clearing away those clouds of mystery and uncertainty which have so long darkened the horizon of medicine. It is not from the communication of new and striking cases, though they are unquestionably of high value, so much as from the careful registration of ordinary facts which are every day passing under the eye of each individual, that important results are to be anticipated. The aggregation of numerous analogous facts frequently elicits unexpected decisions, and often falsifies the conclusions of unrecorded experience; and the results of practice are very differently impressed upon our minds when deduced from a careful registry of the facts which have passed before us, than when drawn from the dim chambers of unaided memory. If but a few practitioners annually published the details of their experience, in an uniform and comprehensive style, how great an amount of information would soon be collected upon various subjects, and how soon would be swept away many of those vague theories and equally uncertain facts which now fetter the minds of practitioners, narrow their views of disease, and embarrass them in their rules of treatment.

It may be asked from what sources this statistical information is to be obtained most easily and with the greatest degree of certainty? The answer to

this would, of course, be—from the hospitals, large and small, in various parts of the kingdom. At the same time, we are compelled to say that this soil, so excellent in quality, has been allowed to lie comparatively fallow and unproductive. Rarely do we see a statistical report at all of the cases admitted into a hospital, and, still less frequently, any thing like an accurate or serviceable one.

And, hitherto, much as we have reason to be proud of the charitable munificence of our nation, and of the unparalleled amount of her voluntary contributions for the maintenance of hospitals for the sick poor, it must be deplored that, with facilities greater than those of any other country, we are inferior to some of our continental neighbours in the precision and punctuality with which they conduct the statistical department of their various medical charities.

It is deplorable to reflect on the great mass of information which in these institutions is literally squandered away, for the want of a little management and a little trouble in collecting it. It is true we have of late seen, now and then, in the public journals, a solitary report or two from the medical officer of an infirmary or hospital, and we rejoice at being able to allude even to these few feeble attempts, as they show that a feeling is beginning to arise of the propriety, we may almost say duty, of those persons who are connected with institutions of this sort collecting and rendering available the scattered materials they present.

It has been one great object with the medical division of the statistical society to effect improvement in this respect; some good results have already been produced, and we trust their efforts will be followed by further improvements. Convinced of “the importance of applying the instruments and

methods of inquiry which have enriched the exact sciences, to vital phenomena,” the committee for prosecuting researches into this department issued some time ago a blank form to the medical officers of several of the London hospitals, and it appears that returns have been made from the Westminster, Middlesex, Charing-cross, King’s College, University College, London, and Dreadnought hospitals. Some of the results of their exertions we published in a former number. It would be premature, of course, to express an opinion of the probable success of their undertaking, but they appear to have started well, and we hope that the medical officers of other hospitals will not be slow to assist them in forwarding their views, and that some uniform method of registering cases may be adopted. Some such principle is sadly required in the metropolitan hospitals, for they have perhaps been comparatively less productive than any others of information of this sort.

While, however, we express our sense of the value of statistical information, as a means of ascertaining various points in medicine, and sweeping away some of the unsatisfactory and ill-founded dogmas which have so long misguided us, and still exert a powerful influence over our opinions, we are not inclined to assent to the opinion of those who fancy that the science and practice of medicine can be reduced to a sort of mathematical certainty and infallibility. So long as men present the same physical and constitutional varieties as at present, it is to be feared that the diagnosis and treatment of their diseases will scarcely be reduced to any such desirable precision.

Unless extreme attention be paid to the accuracy of the details from which statistical results are drawn, they must become positively injurious, in proportion to the weight of authority

which they possess. A statistical return must not be, as we fear is sometimes the case, a cloak for hiding the inaccuracies of a number of collected facts; in order to be of any use at all, it must be of such a nature that each of its details will bear the strictest scrutiny.

A difficulty arises, too, from the various appellations by which different trains of symptoms may be designated. How many terms, for instance, may be used to express the protean disorders of the digestive organs!

These and other difficulties of the same nature must induce those who are inclined to labour in this field of inquiry to do so with earnestness and diligence: they must not fancy that they are conferring a boon on science by producing a jumble of questionable facts, shielded beneath the imposing title of statistical report. Their first endeavour should be to record their observations in a regular and systematic manner, and then to arrange them according to some general rule which seems most convenient.

Hitherto those who have given attention to this subject have been contented with the attempt to ascertain general facts, to point out prevalent forms of disease in certain places, ages, and constitutions, and to ascertain the average rates of mortality in various affections. This is no doubt extremely valuable information, as bearing upon the main causes of disease, and their mode of prevention; and the benefit of it has already in some instances been shown. But we hope soon to see another, and perhaps more useful, though unquestionably more difficult branch of the subject, more fully entered upon: we allude to the statistics of individual diseases, their symptoms, causes, and modes of treatment. Such would be the most effectual way in which each individual can transmit

to others the results of his own experience; and it is from collected facts of this sort that we may expect the science of medicine to be in future most surely advanced. Our neighbours abroad have entered upon this course; and every one who is acquainted with the present medical literature of France and Germany knows the advantage they are deriving from it in those countries.

BRITISH MEDICAL ASSOCIATION.

A MEETING of this society took place last week at the British Coffee House: Dr. Webster, of Dulwich, in the chair.

The Chairman, Dr. Grant, of University College, Dr. Marshall Hall, and one or two others, made speeches; but they all "hung fire" most lamentably, and the meeting proved a complete failure; as will be seen by the letter of one of the members, which we subjoin. Professor Kidd and Sir James Clark were elected honorary members; and of the profession in the United Kingdom, on this great occasion of the annual meeting, no fewer than *two* were added to the list of ordinary members!

The only thing during the evening, worth listening to, was the oration of Mr. Grainger, which we gave at full length last week.

To the Editor of the Medical Gazette.

SIR,

ON Tuesday evening last, the members of the British Medical Association held their sixth annual meeting at the British Coffee House, Cockspur-street, and notwithstanding the low price of their cards of admission (3s. 6d.), there was, compared with their former anniversary reunions, a great falling off in numbers, and in the interest which their proceedings seemed to excite. Instead of a long list of candidates for admission, two only were announced; and in vain the perpetual president, Mr. Webster, repeatedly requested the ordinary members to take part in the proceedings, stating that the council, in their great condescension, had left some of the

resolutions to be seconded by those in the ranks: the ordinaries, mindful of supercilious bearing on the part of the president on former occasions, responded not to the gracious permission.

Many persons, deeply sensible of the disadvantages under which our general practitioners labour,—of their state of isolation and non-representation,—of their want of protection and corporate influence, have expressed surprise that this association should have received from them so little patronage and support; that out of thousands of members scarcely one hundred have joined it. Dr. Marshall Hall, in a sensible speech during the evening, particularly dwelt on this topic; but the truth, I believe, is, the great body of surgeons hold aloof from the society, not from apathy, but from a well-founded conviction of its faulty organisation and management, and of its total inadequacy to advance the cause of genuine medical reform,—“Non tali auxilio nec defensoribus istis.” In vain the general practitioners of this country look to this association for a realization of the representative principle, as in truth the only persons there represented are the members of the council, who, from the commencement of the society, have regularly elected each other; and this accounts for several obscure individuals continuing to be re-elected from year to year, solely because they happened to be on the first council,—individuals who, however worthy and useful they may be in the circles in which they move, must themselves be conscious that they are very inadequate representatives of either the talent or respectability of the profession, and who, had they been equally studious of advancing the cause of the association as of indulging their *amour propre*, would long since have retired from a post which they were not qualified to occupy, to make way for abler and more influential men.

The council comprises one-third of the association; they form a compact body, accustomed to meet, and are well known to each other: at the termination of their year of office, therefore, each has only to vote for his thirty-five associates to render the return of them all a matter of perfect certainty; because the sixty or seventy ordinary members are unknown to each other, without union or concert, and very

many of them take no interest whatever in the annual election of the council, from a well-founded conviction that, organised as the society is at present, any attempt on their part to oppose the usurping party would be useless and unavailing. Hence, in reality, there is no representation in the British Medical Association, the officers and council being as regularly self-elected as those of the much-abused London College of Surgeons; and hence the reason why many respectable and talented practitioners have after a time withdrawn their names, disgusted and disappointed. In order to introduce fairly the representative principle into the Association, and to make it, not as it has hitherto been, a delusion, but a reality, it should be a rule that the council for the current year should have no voice in the election of their immediate successors,—or a part, one-third, or a half, should be ineligible for the year ensuing. But instead of contemplating any reform of this kind, I believe that to propose such to the dominant party would be quite sufficient to taboo any of the ordinary members.

An independent member is almost powerless as to effecting any alteration in the constitution of the Association, as it is one of the rules that notice in writing of a proposition for change must be sent to the secretary a month previously to the March meeting. Thus the whole power of the council would be organised against any motion disagreeable to them; and from what I have heard and observed of their animus, I believe the mere circumstance of an improvement emanating from one of the ordinary (as all those not of the council are politely termed) would be quite sufficient to elicit the hostility of the governing body.

With all its faults, however, the British Medical Association has made some moves in the right direction; and had its organization and management been less defective, would, I believe, at present have been a powerful, numerous, and flourishing body. But an association of medical men, single-mindedly studious of benefiting the public, and of elevating and ameliorating their profession—free from party politics and from paltry cliquism—based on broad and general principles—fairly and honestly recognising the

representative principle, has yet to be formed. Let but such arise, and I venture to predict there will be no apathy on the part of general practitioners in joining its ranks; and as they are enlightened as to their grievances, and determined to remove them, and deeply sensible of their unjust exclusion from corporate influence, so will speedily their talents and weight and influence be brought to bear successfully and irresistibly against the strong holds of monopoly and corruption.

I am, sir,

Your very obedient servant,

JAMES LEESON.

Finsbury Square, Nov. 11, 1842.

LIFE ASSURANCE FEES TO MEDICAL REFEREES.

A MEETING of the following medical practitioners of this town was held at the Lion Hotel, Shrewsbury, on the 25th of October:—Dr. H. Johnson, Mr. Arrowsmith, Mr. W. J. Clement, Mr. Dickin, Mr. Clarke, Dr. Drury, Mr. Gill, Mr. Wood, Mr. Griffiths, Mr. Keate, Mr. Onions, Mr. Bratton, Mr. Cartwright, Mr. Crawford, Mr. Heathcote, and Mr. Foulkes. In consequence of the unavoidable absence of Rice Wynne, Esq. Dr. Johnson was called to the chair, and having briefly explained that the object of this meeting was to adopt some resolution respecting the payment of fees by Life Assurance Companies—

Mr. Cartwright rose and proposed a resolution to the effect that they pledged themselves not to answer the inquiries of Insurance Offices, unless accompanied with a fee of one guinea. It was evident, he said, from the frequent publications in various periodicals, and from the present meeting, that the system adopted by Insurance Offices of obtaining medical certificates was practically wrong, founded on erroneous, and, in his opinion, dishonest principles; at any rate, the system was highly offensive to the feelings and injurious to the interests of the profession. As the Offices had not acted in a conciliatory spirit, but had uniformly met their remonstrances with indifference and slight, surely they had a right, and ought, in self-respect, to pass such regulations as might conduce to their own convenience and interests. He then drew their attention to the distinction between a medical referee and a medical attendant. The medical referee was appointed by the Offices, was their agent, and was paid by them; whilst the medical attendant was made, by a rule of the Offices, the agent of the ap-

plicant, and was scarcely ever paid for his services.

[Mr. Cartwright next proceeded to make various apposite remarks, which want of room compels us to omit.]

Mr. W. J. Clement seconded the resolution, expressed his cordial concurrence with the sentiments of the proposer, and trusted they would all see the advantage of acting with unanimity on that most important subject.

A desultory conversation then ensued, during which it was stated, that the London, Edinburgh, and Dublin Office paid £1. 1s. in all cases to the medical attendant, as well as to the medical referee: the Britannia, the Protestant Dissenters and General Life Assurance Company, the Commercial and General Life Assurance Company, and the National Provident Institution, and several other offices, were, in some instances, in the habit of paying the medical attendant.

The resolution having been unanimously carried, the pledge was immediately signed by each gentleman present.

Mr. Cartwright was then appointed hon. secretary to the Association, and requested to send a circular to all the practitioners in the county, soliciting their assent to the above resolution. Thanks were then voted to Mr. Cartwright and Dr. H. Johnson, respectively; to the former for his zeal and activity in obtaining much valuable information, which had materially contributed to the success of the meeting, and the latter for his able services as Chairman.

The following gentlemen, who were unable to attend the meeting, have since signed the resolution—Mr. Wynne, Mr. Clement, Mr. Piddock, and Mr. Stevens.

MIDDLESEX HOSPITAL.

Extirpation of a fatty tumor from the neck.

JOHN HILL, æt. 54, was admitted under Mr. Shaw, with a tumor on the left side of his neck. It was situated in the space between the sterno-cleido-mastoideus and the trapezius, and reached from behind the mastoid process of the temporal bone to the middle of the clavicle. Its form was oval, and slightly lobulated. It projected, at its most prominent part, about four inches from the level of the neck. The posterior edge of the sterno-cleido-mastoideus overlapped it in front, and it was bound down by the platysma myoides; yet its attachments at its base were loose. No large vessel could be discovered in close connection with it. The skin was moveable upon the tumor, except at its most projecting part, where there was an extensive cicatrix; and here

the skin was thin, and firmly adherent. The patient suffered no pain in the swelling. On grasping it, it had a feeling of solidity throughout its general mass; yet there was a softness and elasticity in its more superficial part which gave the impression that the tumor consisted of fat. The patient first observed the swelling so far back as twenty-five years ago, and it was not long of acquiring its present size; since which time he has had no further inconvenience from it than as a deformity. About twelve years ago, by his wife's persuasion, he applied a quack salve to the tumor, in order to disperse it: the effect was, that a portion of the skin mortified, and the scar seen on its surface was produced.

Having been kept in the hospital a few days, and some purgative medicine administered, the operation of removal of the tumor was performed, October 14th.

Two elliptical incisions were made in the length of the tumor, so as to include the cicatrix mentioned above. The anterior flap was turned aside first. In effecting this, a layer of dense fascia, consisting principally of the platysma myoides altered in structure, was cut through; and then the cellular attachments of the tumor were found to be comparatively thin and delicate. These were divided by directing the edge of the knife upon the tumor, and pulling the tumor, at the same time, forcibly to one side, in the manner employed when cleaning the fibres of a muscle in dissection. Only one small vein was opened in the course of turning out the tumor from its bed. The chief adhesion was at the superior part; and when this was cut through at the last, a small artery, requiring ligature, was divided, and also a branch of the superficial cervical plexus of nerves, which passes to the occiput. The edges of skin were brought together by three sutures. In the course of a few hours after the operation the wound was dressed by placing a strip of simple dressing over the line of the incision, laying a long narrow compress of lint on each side, and securing these by adhesive straps: a pad of cotton wool was then put over all, and secured by calico roller round the neck. The patient did not utter any expression of pain during the operation, and walked back to bed without assistance. The tumor weighed three-quarters of a pound, and it consisted wholly of fatty substance, without any distinct cellular envelope. The patient was ordered—

Hydrarg. Chlorid. gr. iii.; Extr. Colocynth. Co. gr. vi.; Antim. Pot. Tart. gr. ʒ. Hora somni.

On the fifth day his health was so good, and the wound was so near being healed, that he was allowed to sit up.

October 25th.—There being only a small

part of the wound not united, he was made an out-patient.

Post-mortem appearances in a case of dislocation of the shoulder, four days after reduction.

A coachman, who fell from his box and suffered compound fracture of his right leg, and also dislocated his right shoulder, was seized with delirium tremens, and died five days after the accident. The humerus was reduced without much difficulty, by raising the elbow above the level of the shoulder, and then directing the head of the bone into the socket, the surgeon using his forearm as a fulcrum, and suddenly depressing the patient's arm.

On removing the integuments from around the shoulder, considerable ecchymosis was observed in the posterior fasciculus of the deltoid muscle; and there was also a slighter appearance of the same kind in the anterior part of the muscle. The deltoid having been cut across transversely, pus was found in the bursa situated beneath it near its insertion. Upon exposing the articulation, by dissecting off the superior part of the deltoid, a laceration of the capsular ligament, of about an inch in length, and close to the greater tubercle of the humerus, was brought into view. The chief part of the greater tubercle was torn off, in the form of a thin shell of bone, from the head of the humerus. This was obviously produced by the supraspinatus, infra-spinatus, and teres minor muscles, which are inserted in common into that process, having been put violently upon the stretch when the dislocation occurred; and the rent in the ligament must have taken place from the same cause, owing to the tendons of those muscles being inserted likewise into the capsule. The tendon of the long head of the biceps preserved its place in its proper groove; but it was nearly torn completely through, two-thirds of it, at least, being either torn or in loose shreds, while the remainder was softened in its structure. Nothing deserving of note was observed in the short head of the biceps, coracobrachialis, and the pectoral muscles, or vessels and nerves, except a slight ecchymosis in a few points. The subscapularis muscle also appeared uninjured. The dissection was now prosecuted by carefully detaching the capsular ligament from the humerus, cutting it close along the cervix. No additional laceration, besides that already noticed, was seen, till the glenoid surface of the scapula was disclosed; when it was found that the capsule had been completely torn from the inner edge of this cavity. By putting the fingers into the rent thus formed, and tracing the boundaries of the cavity into which it led, it could readily be ascertained where the head of the humerus had lodged when it was

displaced: it must have lain directly upon the cervix, and part of the venter, of the scapula, just under the root of the coracoid process; and the fibres of the subscapularis muscle, where they converge to be inserted into the lesser tubercle of the humerus, must have covered it on its inner side. The synovial membrane of the joint was stained of a brown colour, from the effects of the effused blood, but was not otherwise much altered in structure.

Post-mortem appearances in rupture of the tendo-achillis, six weeks after the accident.

John Lennard, æt. 48, was admitted under Mr. Shaw's care, September 16th, with rupture of the tendo-achillis of the left leg. The foot was secured in the usual position for that accident, during five weeks. At the expiration of that time he was suddenly seized with acute bronchitis, and died on the 28th October, six weeks from the day of his meeting with the accident.

The tendon was removed for more careful examination. It was found that the injury had occurred two inches above the os calcis. There was slight condensation of the cellular membrane and adipose tissue immediately investing the tendon, where it had been ruptured. Having cleared this off, the surface of the tendon, on its posterior or superficial aspect, was continuous from the sound part above to that below; while, on the anterior part, there was a depression, caused by the separation of the ruptured fibres from each other and the space between them being imperfectly filled up. When a longitudinal section was made through the injured part, it was apparent that the rupture of the fibres of the tendon had not been complete; that a layer, amounting to about an eighth of an inch in thickness, situated on the posterior aspect, had escaped being torn through, while the remainder of the fibres had been ruptured, and drawn apart from each other to the extent of an inch. Each ruptured end was of an irregular conical shape, and was distinguished by a bright red colour, caused by effusion of blood, which retained its florid hue, among its fibres. This redness was greatest along the margins of the torn fibres; and was in striking contrast both with the glistening whiteness of the sound part, and with the colour of the substance which formed the medium of union between the ruptured ends. The interposed new structure was of a dull brown colour, slightly reddish, and was about half an inch thick. It was harder and more inflexible, and offered greater resistance to the knife in cutting it, than the adjoining sound tendon. On holding it in a particular light, faint indications of a striated appearance on its surface could be

discerned, but it resisted attempts to divide it by lateral separation into distinct longitudinal fibres, which is so readily effected in properly developed tendon. After a few days' maceration in water, the brown colour characteristic of this part became of a lighter hue, approaching to yellow; and several white longitudinal fibres, similar to those existing in common tendon, could then be seen scattered within it. A portion of the tendon was submitted by Mr. T. Wharton Jones to microscopical examination, and he has kindly given the following report of his observations:—

"The substance uniting the ruptured tendon, firmer than cellular tissue, less compact than tendon, is not unlike the tissue of fibrous tumor. It consists of fasciculi of fibres, closely arranged, and interwoven like a felt work. It cannot be teased out so easily as tendon; and the fibres that are isolated do not present such an even contour as those of regular tendon. Acetic acid, without reducing the tissue to a uniform jelly, as it does cellular tissue or tendon, rendered the fibrous structure more transparent, and thus brought into view nuclei in various stages of elongation into nucleous fibres. The yellowish red colour of the new tissue is owing to numerous minute orange coloured corpuscles dispersed throughout its substance."

OBSERVATIONS ON SOME OF THE SIGNS OF LIVE AND STILL BIRTH,

IN THEIR APPLICATIONS TO MEDICAL
JURISPRUDENCE.

By DR. BECK.

[Concluded from p. 239.]

2. THE HYDROSTATIC TEST.—This test is founded upon the difference in the specific gravity of the lungs before and after respiration. In other words, lungs which have respired will float in water, while those which have not respired will sink. Every observation which I have been enabled to make has confirmed me in the general accuracy of this test. It is liable, however, to certain fallacies or objections, which require to be understood, to enable us to make correct application of the test. On the one hand, lungs which *have not respired* may float from *putrefaction*—from *artificial inflation*—from *emphysema*; while, on the other hand, lungs which *have respired* may sink from disease, or from the respiration being *feeble or imperfect*. Of these I shall only notice two, as they are the only ones of which illustrations have occurred in the cases which I have examined. They are, however, the most important of all the objections.

a. Putrefaction. That the lungs of a child which has not respired may float in consequence of putrefaction, although at one time questioned, is beyond doubt. The case which I shall presently relate, independent of numerous others, establishes this fact. The modes of distinguishing it from the floating of respiration are simple and obvious.

a. By the air bubbles being visible under the external covering of the lungs. In vital respiration this is not the case. *b.* By the ease by which the air can be pressed out of the lungs. By simply squeezing them in the hand, they can readily be made to sink in water. In vital respiration this cannot be done. *c.* By the sinking of the internal portion of the lungs. The air, in putrefaction, forms on the surface of the lungs; and hence the internal part, if cut out and put into water, will not float. In vital respiration, the internal part will float more readily than the external part of the lungs.

Case.—Aug. 25, 1838. A still-born child was presented for examination by Dr. Wilson, of Bellevue Hospital. The child had been born two days before. The weather being intensely hot, decomposition had commenced. The body was of a greenish colour; the abdomen greatly distended; the skin peeling off in several parts of the body. The cord about two inches long, smooth, soft, and flexible; weight, 31,680 grains; length, 22 inches; the umbilicus twelve inches from the top of the head—the centre of the body, accordingly, a little above the umbilicus. On opening the chest, the surface of the lungs was found covered with air bubbles, varying from the size of a large pea to a pin's head. On the posterior part of these organs there were no air bubbles. The colour of the lungs was dark red, with here and there spots of a lighter hue. The lungs taken out of the chest, with the heart and thymus gland attached, floated in water; separated from the heart and thymus gland, they also floated, as did also the latter organs. The weight of the lungs was 540 grains; making the relative weight to that of the weight of the body as 1.58. A portion of the internal part of the right lung being cut out, sank in water. Each lung was now cut into ten pieces, and on being put into water, some sank, while others floated. On being moderately compressed between the fingers, each separate section sank rapidly to the bottom of the vessel. The ductus arteriosus was cylindrical in shape, and about the size of the pulmonary artery; the foramen ovale open; the umbilical vessels and ductus venosus pervious; and meconium in the large intestines.

This case illustrates, very strikingly, the fact that the lungs of a still-born child may float from putrefaction, and at the same

time confirms the accuracy of the tests by which it may be distinguished from the floating which is the result of vital respiration.

b. Artificial inflation.—That the lungs of a child which has not respired may be artificially inflated, so as to cause them to float, though doubted by some, is well established; and when this is the case it presents one of the most puzzling problems—to distinguish it from vital respiration. The only test upon which any reliance can be placed is the application of suitable pressure to the lungs. If the floating be the result of vital respiration, no degree of pressure can expel the air from the lungs sufficiently to cause them to sink; while, on the other hand, in cases of artificial inflation, this can be done.

Case.—Dec. 6, 1837. Examined a child which had been still born, but which the accoucheur had attempted to resuscitate by blowing into its mouth, but without success. Length, twenty inches; the centre of the body at the umbilicus; head full of hair; nails full grown, and the body perfectly sound; weight, 47040 grains. No inflammatory circle around the navel; thorax flat. On opening the chest, the lungs were found in the upper and lateral portions of the chest, leaving the pericardium and diaphragm uncovered. On taking out the lungs, the *right* lung was of a dark red colour, with the exception of the lower part of the upper lobe, and the upper part of the lower lobe, which were of a bright red. Distinct crepitus in both lungs in the parts corresponding to the bright patches. The weight of the lungs was 900 grains, making the relative weight to that of the body as 1:52. Both lungs floated in water. The separate lobes of each lung also floated. The right lung was then cut into twelve pieces, all of which floated; but all the pieces sank after being subjected to pressure. The left lung was cut into ten pieces, and all but one floated. On pressure being made they all sank. The pressure was made by placing them in a piece of strong linen, and then twisting and wringing them; after this they were placed under a large flat stone.

The ductus arteriosus was as large as the trunk of the pulmonary artery, cylindrical in shape, and much larger than the branches of the pulmonary artery. The foramen ovale, ductus venosus, umbilical arteries and veins, all open.

This case is exceedingly interesting, as illustrating the effects of artificial inflammation, and as showing how nearly they resemble those of vital respiration. The floating of the lungs was almost perfect, and the weight of the lungs (900 grains) was nearly that of the usual average standard of children that have respired. On the other hand,

the sinking of the lungs, after due pressure, the relative weight of the lungs and the body, 1:52, and the state of the ductus arteriosus, were in favour of artificial inflation.

3. STATE OF THE DUCTUS ARTERIOSUS.

—This is called the *Vienna test*, from its being originally suggested by Prof. Bernt, of Vienna. It is founded on certain changes which take place in the ductus arteriosus immediately after respiration. In the mature fœtus before respiration, this duct is about half an inch long, cylindrical in shape, with a diameter about equal to that of the pulmonary artery, and more than double the size of the branches of that artery, each of which is equal to that of a crow quill. If the child have respired a few moments, the duct becomes conical in shape, with its contracted part towards the aorta. If the child have respired for some hours or a day, it becomes cylindrical again in shape, but lessened in length and diameter. It is much less now than the pulmonary artery, and not larger than the branches of that artery. If the child have respired for several days or a week, the duct will be found still more contracted; its diameter will be not larger than a crow quill, while the branches of the pulmonary artery are much enlarged to the size of a goose quill.

The result of my observations goes strongly to support the accuracy of these observations. In six still born children, I found the ductus arteriosus cylindrical in shape, and about the size of the main trunk of the pulmonary artery, and considerably larger than the branches of the pulmonary artery—in some cases double the size. In a seventh still-born child, I found it nearly the size of the pulmonary artery, but not much larger than its branches. In a child which had lived four days, the ductus arteriosus was cylindrical, three lines in length, and about the size of a crow-quill, and not more than half the size of the pulmonary artery. In a child which had lived three days, the ductus arteriosus was about two and a half lines long, and cylindrical, about one third the size of the pulmonary artery and somewhat smaller than the branches of that artery. In a child which lived forty-six hours, the ductus arteriosus was one-fourth of an inch long, cylindrical in shape, less than half the size of the pulmonary artery, and about equal to the branches of that artery.

Although the foregoing observations, generally speaking, confirm the accuracy of this test, it is to be recollected that it is not to be relied upon in all cases. This has been shown particularly by Orfila.

I have thus, as briefly as possible, recorded the results of the foregoing observations, without indulging in the many comments which naturally suggest themselves. I have,

however, in another place,* so fully discussed all the points connected with this subject, as to render them at present unnecessary.—*Trans. Med. Soc. State of New York*; and *American Journal of the Med. Sciences*.

DALBY'S CARMINATIVE.

R Tr. Opii. ʒj. ; Tr. Assafœt. ʒiiss. ; Olei Carui. ʒj. ; Olei Menth. Pip. ʒij ; Tr. Castorei, ʒviss. ; Sp. Rectif. ʒvj.—
M. S. A.

When the mixture is complete, it is to be divided into two-drachm doses, which are to be poured into small bottles containing from seven and a half to ten drachms a-piece, into each of which a drachm of calcined magnesia has been previously introduced. Finally, the bottles are to be filled up with simple syrup, and a small quantity of rectified spirits, and to be well shaken to mix the whole.

This medicine is one of the most ancient and popular arcana in Great Britain, where it is recommended in the flatulence, gripes, convulsions, &c. of infants; and in the irregular gout, the bloody flux, and violent colic of adults. It is thought eminently serviceable in the different bowel complaints to which sea-faring men are very subject.

Five or six drops are given to weakly infants two or three days old, in a tea-spoonful of warm water sweetened; and if this dose does not produce the desired effect in six or eight minutes, it is repeated. The dose is augmented in proportion to the age of the little patients, and the severity of the symptoms to be combated. Two doses in a day, or three at the most, are sufficient for the most obstinate cases.

A tea-spoonful is given to infants from one to two years old, or even more if the symptoms are violent. Three tea-spoonfuls are given to children seven years old.

Adults take half or two-thirds of a bottle for a dose, either pure, or mixed with as much warm water as will make it of an agreeable temperature. In all cases it is necessary to shake the bottle before pouring out the dose.

It has been observed that in persons subject to constipation, or who often vomit acid matter, it is very useful to combine magnesia with the use of this carminative.—*Journal de Chimie Medicale*, Sept. 1842.

[Like other popular nostrums, Dalby's Carminative is made after various receipts, so that the dose which is perfectly safe when the cordial is prepared by A, may be poisonous

* *Elements of Medical Jurisprudence*, by T. Romeyn Beck, M.D., and John B. Beck, M.D.

when it is manufactured by B. In the Returns from the Coroners of England and Wales, made to the House of Commons in 1839, we find ten cases of death from Godfrey's Cordial, and one from Infant's Mixture. Dr. John Clarke mentions an infant destroyed by forty drops of Dalby's Carminative.—*Translator's Note.*]

INTRODUCTION OF AIR INTO THE VEINS.

DR. GODEMER, Physician to the hospital of Ambricres, in Mayenne, has published in the Transactions of the Medical Society of Indre and Loire, three cases of tumor in the neck, during the amputation of which a peculiar hissing noise was heard, followed by the instantaneous death of the patient. The only abnormal appearance presented on the examination of the body was the distension of the cavities of the heart by a great quantity of air. In removing large tumors from the neck, or from near the heart, we should avoid anything by which the entry of air into the veins can happen. Among these causes, M. Godemer classes the movements given to the tumor in dividing the circumjacent cellular tissue, with the view of removing the diseased growth whole. To avoid this inconvenience, under these circumstances, he removes the tumor piecemeal, and since he adopted that plan he says he has not lost a single patient by this unfortunate occurrence. Six cases of tumor of the neck were operated on by him in 1839 and 1840, and with success. The patient suffers a little more pain; but in exchange, there is not any danger of the passage of air to the heart, and the consequent immediate death of the patient.—*Prov. Med. and Surg. Journ.*

CASES OF POISONING IN GERMANY.

1. *Poisoning by arseniate of copper, with the successful administration of the hydrated oxide of iron.* By Dr. FIEDLER.

A PIECE of bread and butter, thickly covered with common green paint, having been placed to destroy beetles, a child two years old ate a middling sized bit of it, and soon afterwards vomited violently. After the child had drunk a good deal of milk, it was quiet, but soon afterwards still more violent vomiting came on, the whole body became cold, and the features distorted. The author prescribed the hydrated oxide of iron. When he visited the child five hours after-

wards, he found it sleeping tranquilly; the whole body was uniformly warm, the pulse quiet, and vomiting had entirely ceased. With the exception of a mild diet, no prescriptions were required. Fourteen months have now elapsed, and the child remains quite well, like the one whose case the author reported several years ago.

2. *Poisoning by digitalis.* By Dr. SIEMON DAWOSKY.

A man, about fifty, had been freed from the symptoms of incipient hydrothorax, by the ethereal tincture of digitalis, combined with the spirit of nitric ether, and ethereal oil of juniper. Being again attacked by these symptoms in the autumn of 1841, he derived the same benefit from the same medicine. But after the patient had taken the remedy for about twenty days, the following phenomena came on. The pulse, which, during the former use of the remedies, had lessened by ten or fifteen beats in a minute, now sank almost to half its usual number. Besides this, the patient was tormented by the most painful disquietude, so that, even in the night, he left the bed every moment, could not sleep, and with his eyes open conversed with persons who were not present. At the same time the pupils were dilated, the conjunctiva both of the eye and the lids was red; he had little appetite, with great nausea, and violent thirst, with great dryness of the mouth; the alvine evacuations were scanty, the secretion of urine was increased. These phenomena, which obviously were merely effects of the digitalis, had lasted six days, when the restlessness diminished, sleep returned, and the dilatation of the pupils disappeared. This history should serve as a warning, when one is tempted, as one so often is in diseases of the heart, to use digitalis a long time uninterruptedly.

[We recommend the beginner, as a safe general rule, to use hyoscyamus instead of digitalis, to quell inordinate action of the heart. As a diuretic, there are many excellent substitutes.—*Translator's Note.*]

3. *Poisoning by decayed carrots.* By Dr. LIEBER, of Berlin.

A girl eight years old, who had gone to bed cheerful and well, on awaking complained of headache. Violent vomiting came on, which was quieted by chamomile tea, but convulsions were observed soon afterwards. They continued till noon, when Dr. Lieber was sent for, but he could not see her till after 3. She was lying, without consciousness, on her back, and breathed but faintly; her face was rather puffy; her pulse quiet and full; the bowels not open. Leeches to the head and a clyster were prescribed, but before these remedies could be

used the girl was dead. No cause for the illness could be discovered, except her having eaten a considerable quantity of half-rotten carrots, which had been thrown into the court-yard. A boy belonging to another family, who had eaten of these carrots, was also ill, but recovered after spontaneous vomiting and diarrhoea.

A post-mortem examination, 28 hours after death, confirmed Dr. Lieber's conjecture as to the cause of death.

The membranes of the brain were very full of blood; the brain, which was normal in consistence, was less so; the sinuses, again, were distended with blood. There was no effusion in the ventricles, and the *plexus choroidei* were rather paler than usual. There was no disease in the cavity of the thorax. The external surface of the stomach was unaltered, but on the internal one, particularly at the greater curvature, there were several inflamed spots of different sizes. They were dark-red, and their finest vascular ramifications could be distinctly seen, and could not be washed off with water. Bluish spots were to be seen in the intestines, but only in their peritoneal covering; at least the mucous membrane bore no marks of inflammation.

4. Poisoning by liver-sausages.

Eight persons belonging to the family of a countryman named Ehrmann, at Simmetshausen, were poisoned by eating sausages, in May, 1841. They had been made by Ehrmann from a pig slaughtered a week before, which appears to have been perfectly healthy. The sausages tasted sour, but two of the family ate heartily of them, namely, the countryman himself, a man of 64, and his man-servant, aged 28. They all fell ill two, three, or four days after partaking of them.

The following symptoms were observed in all, in a greater or less degree:—giddiness; great weakness of sight, which gradually increased almost to blindness; double vision, with perfectly undisturbed consciousness; remarkable dryness of the mouth and fauces, the structures of which, with the exception of the tongue, were of a deep red, and covered with elevated points, which were also red; difficulty of swallowing felt below the *pomum Adami*; sensibility of the epigastric region; vomiting; diarrhoea; griping; paralysis of the eyelids, so that the patients could not open their eyes; enlargement and immobility of the pupil; a bluish reddening of the sclerotic; a lisping utterance, difficult to be understood; constant decubitus on the back, with a perfect capability of putting out the tongue; entireness of the mental powers, the hearing, and voluntary motion; and a pulse of tolera-

ble strength, but slightly quickened, and only occasionally intermitting. Moreover, there were paroxysms of suffocation on attempting to swallow even fluids, stoppage of urine, and, lastly, frequent, deep, sighing respiration, with rattling in the larynx and the chest.

Three of the patients, who had eaten most heartily of the sausages, died; Ehrmann on the fourth day of the fatal supper, the servant also on the fourth day, and one of the countryman's sons, aged fourteen, on the ninth day. Another son, aged eighteen, had not recovered perfectly till the expiration of four weeks. The dissection of the three who died gave the following results. On the surface of the dura mater there were a number of drops of deep-red blood, while the other membranes showed no superabundance of blood, but were rather pale. There were abscesses of the size of a pea, filled with thick, whitish pus, in the tonsils. The pharynx was bluish-red, the epiglottis pale, the *rima glottidis* wide open; the larynx was slightly reddened on its inner and upper surface, while immediately below the larynx the whole inner and upper surface of the trachea was of a dark bluish red, in consequence of close-set vascularity and angillations. This colouring had a speckled appearance, from the interposition of spots which were not so dark. Towards the division of the bronchi the colour was deeper still, and extended into all the bronchial ramifications, which, when cut through, sent forth dark frothy blood. The lungs, particularly in their posterior and inferior parts, were filled with very dark blood, did not crepitate there, had a velvety appearance on the cut surfaces, and were nearly in the same condition as one finds them after typhoid diseases. In the patient who died first, the heart was wasted and brittle; and in the other two it contained several yellow polypi; and, in one of the two, the ventricle contained a small, in the other a larger, quantity of serous fluid.

In all three cases the liver was of a leaden colour in the left lobe and on the lower surface; in the interior it was of a pale brown, and brittle, with the exception of the third case, in which it was of the usual firmness.

In the old man and the servant the spleen was softened (*malsch*) and nearly double the healthy size; the inner surface of the œsophagus was not reddened, but, on the contrary, lined with a white substance like smegma; the cardia also was not reddened, but the fundus of the stomach was of a dark red. In the stomach of the son aged 14, besides several specks of a dirty pink, which scarcely differed from the physiological state, there was a spot several inches in circumference, so soft that when touched it broke into a

a hole. The inner surface of the small intestine, which contained a yellow fluid, was, in one case, of a dark and dirty gray, in another blackish, as if besprinkled with ink powder; in the third, reddish, with minute spots. The external surface of the intestinal canal was of a dirty grey, and in part reddish colour, as it happens after slight inflammation. The colon was extremely dilated, and the cæcum was stuffed with greenish-yellow faeces into the semblance of a thick ball.

Of all the remedies which the author used, the aqua oxymuriatica (solution of chlorine) alone seemed to be of advantage.

Dr. Röser hopes that organic chemistry may come to more satisfactory conclusions respecting this destructive poison of sausages. — *Schmidt's Jahrbücher*, August 1842.

[We have abridged the last case considerably.—*Translator*.]

INJURIOUS DYE FOR THE HAIR.

DR. A. TH. BRÜCK, of Osnabrück, thinks that a violent ophthalmia, under which a lady of 46 was labouring, might be attributed to a dye which she had used during several years for her hair. It is sold at Cologne, under the name of *Poudre d'Italie*, and has been shown, by chemical analysis, to consist of lead and lime.—*Schmidt's Jahrb.*

PROFESSOR OWEN.

WE are happy to announce that a pension of £200 per annum has been bestowed on Mr. Owen, in consideration of his laborious exertions in reference to the Hunterian Catalogue. The reward has been well merited, and we hope will be long enjoyed.

MIDDLESEX HOSPITAL.

WE regret to announce that Mr. Mayo has been compelled, by the state of his health, to resign the office of Surgeon to Middlesex Hospital. Mr. Shaw, who has for some time been Assistant-Surgeon, will, almost as a matter of course, be elected in Mr. Mayo's place. Several gentlemen are in the field for the Assistant-Surgeony.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE VII.

*On the human ovum, in the first month of
pregnancy.*

THE human embryo is enclosed within a sac, to which it is attached by the umbilical cord. This sac is composed of three distinct membranes—the amnion, the chorion, and the decidua. The decidua is the outer membrane, the chorion is the middle, and the amnion the inner. If you cut open a gravid uterus in the early months of pregnancy, as in this preparation, you will observe the decidua adhering to its whole internal surface. On dividing this membrane, you will then see the entire space between the decidua and membrane of the chorion occupied all round the ovum by the placenta and villi of the chorion; and on laying open the membrane of the chorion, from the outer surface of which all the villi extend to the decidua, the amnion will come into view, which immediately encloses the embryo and liquor amnii, and forms the sheath or covering of the umbilical cord: you will also see the vesicula umbilicalis, situated between the amnion and chorion, a short distance from the insertion of the umbilical cord into the membranes.

There are upwards of thirty human ova of different ages, from the latter part of the first month to the commencement of the fourth, now placed upon the table before you. There are only three of these which undoubtedly belong to the first month, but none of them are perfect ova, the chorion and its contents in all of them having been

expelled, and the deciduous membranes left within the uterus.

In the first specimen, the age of which could hardly have exceeded twenty days, and which is about the size of a common hazel-nut, you see the whole is covered with the villi of the chorion. On one side the villi are more luxuriant than on the other, but there is no part of the membrane of the chorion smooth, or destitute of villi. Within the cavity of the chorion which has been laid open, you see the vesicula umbilicalis about the size of a small pea, and closely adhering to it is the embryo, enclosed within the transparent amnion, and which is rather smaller than the vesicle. The embryo is not quite two lines in length, and is much bent. It resembles exactly this figure of a very young embryo contained in Socmmering's plates. There is a space between the amnion and the inner surface of the chorion which is occupied by a soft reticular texture, in which is imbedded the vesicula umbilicalis. This is probably one of the most healthy human ova which has yet been examined. In a second specimen of the human ovum nearly of the same age, which was expelled in abortion, the entire surface of the chorion was covered with villi. The cavity of the chorion likewise contained the vesicula umbilicalis and amnion, but there is only an opaque spot seen within the amnion, and no distinct embryo. In a third ovum, belonging also to the latter part of the first month, you see there is no difference between the appearance presented by the villi of the chorion, in this, and in the other two specimens, which you have now examined. But the cavity of the chorion contained only the vesicula umbilicalis, which was imbedded in the common soft reticular texture always found in this part of the ovum. By the slightest touch the vesicula umbilicalis was detached from the chorion, and it now floats loosely in the spirit of the preparation. There was no embryo or amnion, that I could discover, within the chorion.

M. Velpeau has given the representation of an ovum without the decidua which he believed to be only eight or twelve days old. The whole was covered with villi of the chorion, and was about the size of a common pea. There was neither embryo, amnion, nor vesicula umbilicalis, contained within the cavity of the chorion. He has also given a figure to represent another ovum, the age of which he fixes at twelve days. It had the same size and appearance externally as the other, and within the chorion he saw the embryo and vesicula umbilicalis imbedded in a soft reticular texture which filled the greater part of the cavity of the chorion.

In the Philosophical Transactions of 1837, Mr. T. W. Jones has described a human ovum which was probably not more than three or four weeks old. On laying open the ovum, by carefully cutting and reversing the bald side of the chorion, the following appearances presented themselves. The whole cavity of the chorion was filled with a fine gelatinous cellular tissue, imbedded in which,

towards one extremity of the ovum, was a small round body. It was evidently the vesicular blastoderm, or germinal membrane; on being taken out and examined by the microscope, it presented the same friable globular structure found in the vesicular blastoderm of the rabbit. There was no vitellary membrane to be seen. The chorion of this ovum was expelled with the decidua, and lay in the middle of one of the parietes of the decidua, rather near its upper edge, and was the size of a large pea. One side of the chorion was smooth, the other shaggy, with the villi of the chorion, which leads me to think that this ovum was not in a perfectly healthy condition, and that development had been arrested some time before its expulsion.

The subjoined figures (1 to 7) from Mr. T. W. Jones, represent the natural appearance of this ovum and the ova of the mammifera, after impregnation.

Fig. 1, an ovum found in the fallopian tube of a rabbit the third day after impregnation, magnified forty diameters.

Fig. 2, the ovum of the frog when recently laid, magnified two diameters.

Fig. 3, the ovum of a water-newt, in which development has commenced, magnified rather more than twice.

Fig. 4, a diagram shewing the embryo of the newt after the vitellary membrane has given way, contained only within the cavity of the sub-

stance, which is added to the ovum in the oviduct.

Fig. 5, a diagram shewing the embryo of the frog still surrounded by the vitellary membrane, as well as the gelatinous substance, which is added to the ovum in the oviduct.

Fig. 6, an ovum found in the horn of the uterus of a rabbit seven days after impregnation, magnified forty diameters.

Fig. 7, a human ovum thrown off at the third or fourth week; natural size.

Prof. Wagner has described and given a representation of a normal human ovum of the third week, covered by the uterine decidua,

and which measured about seven lines in length. The subjoined figures represent this ovum of the natural size, and also magnified.

In this diagram is represented a human ovum of the third week (about twenty-one days old) enclosed in the decidua, size of nature, and considered by him to be in a perfectly normal state.

This is a diagram of the same ovum, with the chorion laid open: the embryo, about two lines long, closely surrounded by the amnion.

In this figure the same ovum is magnified: all the parts are designed from nature. The chorion is laid open and reflected, and the albuminous space betwixt the amnion and chorion are represented, and also the umbilical vesicle communicating with the intestine, the heart, lower jaw, ear, hemisphere, corpora quadrigemina, liver, eye, and the two branchial fissures.

The figures subjoined represent an embryo described by Müller, in Meckel's Archiv. 1830, tab. xi. The length of the embryo was $3\frac{1}{2}$ lines. The ovum was open,

and the amnion torn, when it was obtained. From the umbilical vesicle the long pedicle passed, enclosed in the umbilical cord, into the abdomen of the embryo.

EXPLANATION OF FIGURES.—*A*, natural size. *B*, magnified view. *C*, view still more highly magnified, with the membranes restored, and references to the several parts. He regards it as about twenty-eight days old. *a, a*, Chorion laid open and reflected; *b, b, b*, albuminous space betwixt the amnion and chorion; *c*, amnion; *d*, umbilical vesicle; *d'*, pedicle of the umbilical vesicle; *e*, noose of intestine communicating with *d'*; *g*, heart; *h*, lower jaw; *i*, ear; *k*, cerebellum; *k'*, hemispheres; *k''*, corpora quadrigemina; *l*, anterior, and *m*, posterior extremity; *n*, point where the allantois and chorion have coalesced; *n'*, umbilical cord; *p*, liver; *r*, eye; 1, 2, 3, branchial fissures.

M. Coste has given a description and figure of an early ovum. It was the size of a small hazel-nut. The chorion was distinctly villous, and on being divided the body of the embryo was perceived. It was a line and a quarter long and a line and a half broad, of an oval shape, and presented on the abdominal surface an elliptical opening half a line long. Through this opening there were fixed to the abdominal surface of the embryo the pedicles of two vesicles, one nearly opposite to the middle of the body, the other near the caudal extremity. One of these vesicles corresponds, he thinks, with the umbilical vesicle, and the other to the allantois.

Dr. Allan Thomson has described and figured three early ova, in the *Edinburgh Medical and Surgical Journal* for July 1839. They were all covered with villi of the chorion. One measured a quarter of an inch in diameter. The *vesicula umbilicalis* occupied a great part of the cavity of the chorion. The embryo was a line in length, and had its abdomen closely applied to the surface of the vesicle, with which it formed a common cavity. In another ovum, supposed to be only fifteen days old, the embryo and *vesicula umbilicalis* were attached to the chorion by a soft reticular tissue. The embryo lay almost flat upon the vesicle; the sides of the embryo passing, without interruption, into the walls of the vesicle. The amnion was not seen. In the third ovum described by Dr. Thomson, which was supposed to be about six weeks old, and was malformed, the embryo was one-eighth of an inch in length. The heart hung from the anterior aspect of the body in the form of a looped vessel. The intestine was a straight canal, the mouth being pervious and the anus closed. At the middle of the body the intestine opened, by a wide orifice, into the *vesicula umbilicalis*, which was contracted at its lower part. From the back part of the embryo, a pyriform body projected, by which it was attached to the chorion. The amnion was not formed. The bronchial apertures were visible.

Many of the very early ova described by other anatomists have likewise been malformed or diseased, and it cannot, with certainty, be affirmed that a single ovum, in a state of perfect health, has yet been examined in the first month of pregnancy. No positive inferences can therefore be drawn from them respecting the development of the different parts of the ovum during the first month after conception.

Good descriptions and representations of the human embryo, observes Wagner, one of the best and most recent writers on the development of the human ovum, within the first month from conception, are very scarce.

It is true, indeed, that we have many accounts of diseased ova, of monstrous or distorted embryos, of this period; but instead of aiding us, or advancing our knowledge of the earlier periods of development in the human subject, these accounts are even generally calculated to mislead, and it is therefore well to regard the greater number of them as of no kind of value. Some have said that they have found ova in the tubes, or on their very first entrance into the uterus, and before the separation of the embryo from the germinal membrane. But all statements of this kind yet in existence are, in the highest degree, unsatisfactory: the smallest ova hitherto observed in the uterus, or thrown off by abortion, which, in the present state of knowledge in regard to the history of development, can be allowed to be normal in their formation, or as even departing a little from the rule, have been about three weeks old. Such ova, still surrounded by the decidua, measure about seven lines in length; in the naked chorion they are about five lines long. The chorion is at this time beset externally with small cylindrical hollow villi, which either do not penetrate the decidua at all, or do so to a very trifling extent. The embryo itself is two lines long: it is plainly surrounded by an amnion, which lies loosely but still pretty closely about it, and obviously proceeds from the abdominal laminae. The embryo is curved, and presents anterior cerebral vesicles or hemispheres pretty well developed, and considerable corpora quadrigemina behind them; there is the distinct appearance of an eye, and a rounded offset from the medulla oblongata indicates the acoustic vesicle; several bronchial arches and fissures are also conspicuous; the last of them however, not yet completely formed. The anterior extremities are curved leaf-like processes of small dimensions; there is a cleft in the abdomen still open, from which the amnion is reflected. In this cleft is the heart, consisting of a simple auricle and ventricle; behind the heart is the liver, and under the liver the intestine: where the large and small intestine meet, the canal makes an extensive sweep in the umbilical vesicle, which is now nearly equal in size to the embryo. The embryo, together with the amnion and umbilical vesicle, do not occupy the entire cavity of the chorion; there still remains a considerable space which is filled with a delicate filamentous or arachnoidal tissue; occasionally also with an albuminous fluid. (See figure, p. 275.)

Respecting the mode in which the human amnion originates and is developed, nothing is known with certainty; the views which are now entertained by physiologists on the subject being founded almost entirely upon what is observed in the ova of birds. Dr. Pochels

thinks the human amnion consists at first of a large vesicle, which is unconnected with the embryo, and that the embryo acquires its proper amniotic sac by sinking into this vesicle,—an opinion which is contrary to all the observations made on the ova of other animals. M. Coste thinks the amnion is first formed by the detachment or raising up of the outer covering or epidermis of the embryo. Dr. Allan Thomson believes that it is formed by the union of the cephalic and caudal folds of the serous layer of the germinal membrane in the mammalia, nearly the same way as in birds. In the ova of the sheep, rabbit, and cat, he has examined the amnion in its open state, before the union of its cephalic and caudal folds. There are two opinions at least respecting the origin of the chorion. Some think that it exists within the ovary, others believe that the vitelline membrane constitutes the chorion. Valentin is of opinion that it is formed during the descent of the ovum through the tube, as the egg of the fowl acquires the albumen and shell in its progress through the oviduct. Mr. T. W. Jones, from observations on the rabbit, has proved that the ovum gets covered with a gelatinous substance which consolidates and forms the chorion. Dr. M. Barry has followed Mr. Jones, and his opinions confirm this view.

LUMLEIAN LECTURES,

*Delivered at the Royal College of Physicians
in London, 1842,*

By T. MAYO, M.D. F.R.S

Physician to the Marylebone Infirmary.

LECTURE II.

On Nervous Apoplexy.

Opinion that nervous Apoplexy contraindicates copious depletion, considered. Question, whether apoplexy from compression does not rather contraindicate it. Cases. Defective hypothesis which led to first opinion. Criteria of severe nervous Apoplexia, or Apoplexia gravior, considered, illustrated by insolation. Soothing practice, as opposed to depletory, appropriate to milder forms of nervous Apoplexy. This subject considered in relation to moral, intellectual, and physical excitants.

THE views which are to guide us in the history and treatment of disease may be formed in relation to various aspects of it. The first and most obvious one is that which brings together groups of coexisting or successive symptoms, proceeding in a certain order, and occupying a definite space of time. In this way it is easy to contemplate fevers; though they have been often viewed in one of the other aspects which we shall presently advert to.

But simple coexistence or succession of symptoms does not satisfy us as a basis of treatment; and we soon find a disposition rising in our minds to contemplate groups of symptoms, or to presume a connection between remote symptoms in relation to some more philosophical connecting link; and this link we find either in referring symptoms to some coexisting deviation from normal structure or functions, or in an hypothesis as to the efficiency of some presumed antecedent state.

To the first of these two principles of inquiry we are certainly indebted for the most tangible and definite results, inasmuch as it is the most capable of being submitted to the test of observation. In this way, for example, pathologists have made good and established the order phlegmasiæ; and in this way we are sometimes enabled to trace disease as affecting still the same tissue in *different* organs.

In dealing with the second principle of inquiry to which I have just adverted, namely, the framing some hypothesis on which we may account for the sequence of symptoms, or the affection of the organ which constitutes the disease, medical reasoners have, at different times, shewn every possible diversity in respect to venturesome or moderate speculation. The theory of medicine, as this procedure has been called, at one time has fallen into the temperate hands of a Cullen or a James Currey; at another time, it has been disgraced by a Brown, or rendered vague and fanciful by a Darwin.

I have now to call your attention to an instance of its somewhat mischievous interference in the doctrine of that physician to whose valuable work I called your attention in my last lecture: I mean Dr. Kirkland.

In my last lecture, while giving my tribute of praise to his valuable arguments in favour of a soothing rather than depletory treatment in that apoplexy which he calls nervous, as not being preceded by vascular action or sanguineous effusion, I adverted to his extending that rule to the apoplexia gravior; admitting the general truth of his assumption that this may be considered a nervous apoplexy. I ventured to suggest that his view of the subject, if carried out in practice, would go far to account for the incurableness attributed to that form of attack by Hippocrates, and others subsequent to him; for it would deprive us of our most efficient remedy.

The patient whose case I shall place before you in illustration of this topic, had been living in the workhouse of St. Marylebone before his attack occurred. He was a man of strong constitution and frame, who, it is probable, from his former occupation as a horse-keeper, had lived freely, but for

some time must have been limited in his diet. Having gone to bed in his usual health, he was heard in the night to make some sounds in his throat, which led to his being noticed by the other occupants of the ward. Mr. Allen, the assistant resident practitioner, was sent for; and I am favoured by that gentleman with the following account of the state in which he found the patient, and the practice which he adopted:—

“I was sent for to Joseph Tyler, æt. 62, in the workhouse, on the night of the 11th of November, 1841. I found him quite insensible; pupils much contracted; pulse about 60, and very low; the extremities cold: the right side of the body was affected by convulsive movements, which recurred at intervals of three or four minutes, and lasted about the same length of time: the left side was unaffected. I could not easily ascertain how long he had been in that state. For the last two or three days he had been complaining slightly to those around him of a pain in his head. I gave directions for his removal to the infirmary. When he arrived there, he was in a state of partial collapse: the face and extremities of a pallid blue colour; the pupils still contracted and insensible to light; the pulse was slow and feeble, and the convulsions recurred with much force. As he appeared a strong muscular man, a vein was opened. The pulse improving under this measure, the bleeding was continued, until he had lost about fifty ounces; a considerable quantity being also spilt on the floor, in consequence of the convulsive movements, on which the loss of blood seemed to take no effect. As soon as the pulse began to give way, the vein was closed. The symptoms continued, however, in every respect the same, except that the natural heat of the body had been in some measure restored. Recourse was then had to cupping on the temples. When he had lost about six ounces, the convulsions suddenly ceased, and the pupils began to dilate and contract irregularly. In a short time he started up in bed, endeavoured to mutter something, and looked about him in a bewildered way. The cupping was continued until he had lost twenty ounces; he was then sensible, but could not give a collected answer.”

These symptoms did not recur. The patient was brought under the influence of mercury by my friend Dr. Harrison, whose patient he was, and by whose permission I give this case: and in the space of a month he had entirely recovered.

The late Dr. Warren mentioned to me a case of sudden and violent apoplexy attended by himself, in which, after enormous venesection, the patient recovered at once and entirely. But I am not sufficiently in possession of that case to place it confidently

in the same point of view with that which I have just recorded.

A strong, middle-aged man, went to bed one night in his usual health. His wife was awoke by his throwing out his arm suddenly and violently. She found him insensible, breathing stertorously. A medical gentleman being sent for, found him in this state. Mr. Betts, the cupper, who narrated to me this case, was requested to cup him at the nape of the neck. The pulse was not deficient in force. Fifty-three ounces of blood were removed, and the patient at once recovered entirely.

Now these cases, in the opinion of competent observers, fell under the head of apoplexia gravior. The principle laid down by Dr. Kirkland, against which their treatment and event militate, refers to a theory of causation. He presumes that the sudden and violent shock, understood as apoplexia gravior, is one by which the vital principle is injured; and he therefore, under that influence of theory to which I have adverted, would place them, in respect to treatment, in an opposite category to that class of cases which he well describes as bearing evidence of antecedent vascular action and effusion. Now there is much value in the hypothesis which rescues nervous apoplexy and paralysis generally from depletion; and, therefore, lest it should be damaged by indiscreet generalization, it is the more expedient to point out, that, to the apoplexia gravior, its severer form, that hypothesis does not extend; nay, that this form may tolerate, and even require, a much higher degree of depletion, even than cases of presumed extravasation.

We will assume that there is some antecedent probability in the hypothesis of Dr. Kirkland, as to the “destruction of vital power” in apoplexia gravior; but there is another conceivable hypothesis, far more in unison with the above and many similar cases, namely, that vital power is under a temporary interruption; that, as far as the circulation is concerned, a spasm has occurred arresting its course in the brain. Meanwhile, the heart continuing to perform its functions, this supposition would imply a subsequent danger of congestion *ad tergo*, and a liability to rupture; so that the case, though no arterial action or sanguineous extravasation should precede or accompany it, may require the same treatment in kind as such phenomena would have indicated, and not that soothing or strengthening treatment which the unqualified supposition of a debilitating agent would imply. This important difference, however, requires notice, that, in the former case, that of nervous irritation, we have to prevent; in the latter, that of vascular action and presumed effusion, to obviate also; and possibly, in the former case, we may take, with impu-

nity, a larger quantity of blood than would be justifiable, under apoplexy of the latter kind, in which rupture may be presumed or feared to have already taken place; and in which only so much depletion will be warranted as may check the infiltration of blood, and not, by its abstraction from another channel, exhaust the patient, to whose capacity for outliving the absorption of the effused clot we must mainly look for his chance of recovery.

The practical question lost sight of by those who would deprecate depletion in apoplexia gravior, is not merely what state of the circulating system may have preceded the shock, but what may be produced by it, or be likely to follow it.

I may observe, that Dr. Kirkland himself, while he considers a sedative treatment desirable in such cases viewed as nervous affections, and wishes that opium should be tried, speaks most despondently of its probable results. He does not appear to have put it to any proof himself.

The following case was probably one of sanguineous compression from effused blood, though unfortunately this was not substantiated post-mortem. A large, full, healthy lady, aged 56, who had habitually endeavoured to obviate plethora, and head symptoms resulting from it, by large aperient doses, but never undergone venesection, was leaving her dining-room after her usual hearty dinner, when, having stooped to remove some dust from her dress, on resuming the erect position she complained of vertigo, and walked unsteadily through a gallery which led into the saloon. Soon excessive sickness came on, with some thickness of speech, and in a short time gradually indistinctness of thought, and disposition to coma. Mr. Kelson, of Sevenoaks, having been dining with this lady, was on the spot, and instantly bled her to about twenty ounces. I was sent for, and saw her in about three hours. Sixteen more ounces of blood were taken, a turpentine enema thrown up, and successive doses of calomel given. The pulse, which was oppressed, became softer; in the course of the next morning, the night having been passed in profound coma, it rose, and the coma somewhat diminished. She was then again freely bled till this action subsided,—and with it the slight improvement in respect to coma. On this occasion I was not present. But in the evening of that day I met Dr. Warren and Dr. Paris in consultation; and further depletion was resolved on. The coma still existed, with stertorous breathing, and blowing and puffing, with expanded cheeks. She was again bled. The pulse instantly sunk; and she died in a few minutes. The act from which this attack took its commencement, that of stooping

after a full dinner, and the gradual accession and increase of the cerebral symptoms, had much more the character of vascular rupture, with subsequent infiltration of blood, than of a nervous shock. Sauvages and Portal consider the ‘*crapulous apoplexy*’ to imply sanguineous effusion. A large quantity of blood, it will be observed, was taken away in the treatment of this case. Nothing resulted, as in Dr. Harrison’s case above quoted, either tempting a further extension of the remedy, or giving us the smallest reason to conclude that benefit had been derived from it. Simple debility appeared to result.

I have offered the above remarks, as limiting the too general proposition maintained by Dr. Kirkland, and commented upon in my last lecture, that nervous apoplexy occurring suddenly, and not preceded by evidence of vascular congestion, demands a treatment opposite to the depletory. But what criteria can be proposed by which the apoplectic stroke of arrested circulation may be distinguished from the apoplexy of compression? On this point I will not at present offer more than the following observation. When the extravasation is at once so large as instantly to suspend the functions of the organ, there is probably no criterion. Neither, in a practical point of view, is any wanted. For such a case of compression must be fatal: at least, I may express a belief, that in such a case, unless the asthenic state of the patient manifestly forbids, the taking our chance for the case being one of nervous apoplexy in its gravest form is not unreasonable; in other words, according to the above views, the depleting copiously.

There is a large class of analogous cases, in which this practice is actually carried out on a very large scale, by the most judicious practitioners. I allude to the practice under insolation. I cannot bring this before you either more clearly or more pertinently than in the description given of it, by the late Dr. Dick, in Duncan’s Medical Commentaries. Speaking of disorders witnessed by him in the Carnatic, “there is a species of apoplexy,” he observes, “which seizes the men, when fatigued by marching in the heat of the sun, and proves most fatal to the Europeans. They complain, first, of a great headache, thirst, and some difficulty of breathing; in a few minutes a vertigo and bilious vomiting comes on; they drop down breathless, turn comatose, and unless immediate assistance be given, the face swells and turns almost black; the pulse, which was at first full and quick, sinks, and after some hard struggles they expire. Removing them under the shade of a tree, bleeding them freely in time, and giving them some water, generally relieves them. Now this attack comes on under circumstances by no means warranting an hypothesis of prior vascular

action, such as favours extravasation. The patient is fatigued with marching; he is streaming with perspiration; on the other hand, 'no theory of extinguished or diminished vital principle' is allowed to prevent the full application of the lancet; and it is successful."

That hypothesis, therefore, which prohibits or restricts depletory treatment, in nervous apoplexy, must be confined in its operation to those forms of it in which the apoplectic stroke is of a milder character; and I shall now return to that subject, already illustrated by some cases in my first lecture.

It may probably be assumed of all these attacks of nervous apoplexy, that if they are allowed to run their course, that is, if neither the resources of art nor some analogous relief supplied by nature intervene, they tend to the same termination, namely effusion of some kind. But their chance of arriving at this termination will be widely different according to the precision with which we estimate the point from which the disorder originates. Now this point, or, in other words, the causes of that apoplexy which we are considering, will best be viewed under a threefold division. That is, it may be contemplated in relation to moral, or to intellectual, or to physical antecedents.

When a man in his ordinary state of health, receiving a letter, and reading it, becomes flushed, presently is giddy, perhaps vomits, and soon falls down insensible, or when the fall into temporary insensibility under these circumstances is instantaneous, who can perceive in this phenomenon or series of phenomena any other than a moral influence directly exercised upon that part, which is manifestly its bodily organ? What right have we to make it an element of our hypothesis, in explaining this case, that the communication is effected through the circulating system? Yet is the circulating system eventually affected in this case. For if the patient is not soon relieved, the spasm which has then taken place may terminate in sanguineous effusion, and thus lead to the same conclusion with the most unequivocal cases of originating vascular action. In such a case as this, moderate venesection, or cupping, is often required; unless the more unsanguine temperament of the patient allow the resolution to take place without any removal of the *vis a tergo*, but through the medium of antispasmodics. These cases, which I am drawing from nature, are distinguished from the apoplexia gravior by the contractile state of the pupil, the absence of stertorous breathing, and the presence generally of some indications of the hysterical temperament.

But if we follow a process of intellectual exertion on to its occasional termination in apoplexy, here the sequence of phenomena

places the case in a state much nearer to the apoplexy form of compression than to any nervous form of the disease. The excitants applied to the cerebral system are less intense than in the cases last supposed. They operate by repetition. The case indeed rarely comes before the physician until it has arrived at a state of congestion, indicated by a sense of gradually increasing fulness, weight in the head, inability to collect the thoughts, failure of memory, and lethargic tendency. These phenomena place it out of the category of nervous affections, according to our hypothesis. There is no shock of a milder kind occurring antecedently to the vascular fulness, and removable by a mere antispasmodic treatment, agreeably to the views propounded in my first lecture; nor is there one of the more vehement kind authorising in appropriate subjects large depletion. The case must be treated on the principles applicable generally to compression.

Viewed, however, as requiring generally the same treatment with apoplexy from compression, a treatment of which depletion must form a part, there are reasons why the apoplexy threatened by severe intellectual labours should be treated less "heroically" than other forms of such apoplexy. In the cases of that kind which I have witnessed or known of, there has existed a depressed state of nervous energy, which under active depletion is very apt to convert the threatened apoplexy into either mania or dementia, according as the temperament of the patient is sanguine or nervous. Such was the threat held out by the leading symptoms of a young man, who had just past his final examination as a cadet, at Woolwich last year, and came under medical attendance, owing to its effects, the next day. His severe mental affliction had continued for many months. For some days he seems to have been in an unsteady state of mind; and he described his recollections of what had taken place as confused, though he had been successful. His face was flushed and distended; his head uneasy, not heavy; his tongue moist, thickly coated, white, its edges very red; his skin hot; his manner puzzled, and not natural; his epigastric region was tender and painful; his abdomen soft. Some leeches were applied to the epigastrium, and a dose of five grains of calomel given, which was followed by an aperient draught, the operation of which indicated neither accumulation nor disordered biliary secretion. In the evening I was sent for in haste; the bewilderment of his mind was then apparently increasing. It was not delirium; no extravagancy or incoherency, but confusion and enfeeblement; his tongue had become dry and very white. I took no depletory measures. Quiet, mild mercurials and aperients, obviated whatever risk there

may have been of mischief from congestion, and did not incur that of demence. In about three weeks he recovered.

The temperament of this gentleman was rather sanguine; his make athletic and vigorous.

With these brief remarks on the tendency to nervous apoplexy arising from moral and intellectual causes, it is my present purpose to dismiss these topics.

With regard to the physical causes of nervous apoplexy, viewed specially in relation to the question of depletory or antispasmodic practice, whatever distinctions are here made, a large space must be left for those cases in which none can be confidently laid down. In many of these cases we shall find exhaustion from causes which have reduced nervous energy. Such appeared to be the case in the apoplexies immediately preceding accouchement, mentioned in my first lecture as successfully treated by laudanum. The patient has, perhaps, led an intemperate life; he has indulged in sensual habits; he has, perhaps, been shaken by medicinal treatment. In some cases the nervous structure of the brain may be primarily affected by the circulation, not as excessive in general quantity or local congestion, but as containing ingredients to which it has no right, or losing those which normally belong to it. This influence would be analogous to asphyxia.

As I am here suggesting limitations to depletion, I will notice a case, which might otherwise have better come before us when the more vehement form of nervous apoplexy was under discussion. And as I then gave an example of large depletion successfully carried out in a person of intemperate habits, but vigorous and unexhausted constitution, this example will tell us how little can be borne under opposite circumstances, in the same apparent affection. Mr. P. a gentleman aged 63, of a strong frame and originally a good constitution, had filled a high legal office in India. Six years before he consulted me, he had undergone an attack of fever, in the course of which he was salivated, and continued in this state for a considerable time, with a gradual accession, under it, of nervous trembling, numbness of limbs, and occasional failure of thought and memory, and temporary confusion of mind. Under excitement there occurred a degree of irritability in the bladder almost amounting to incontinence of urine, which was limpid and clear. His tongue was red and dryish, his appearance pallid and unhealthy. The pulse and action of heart normal; and there had never been œdema or ascites. I regulated this gentleman's digestive organs by mild aperients, and gave him tincture of valerian in camphor mixture and compound aloetic

decoction, allowing a moderate use of wine, which, in former periods of his life, he had taken freely but not excessively. On this plan his symptoms were mitigated. But about three months afterwards, I was sent for to see him under different circumstances. He had come up to London in his usual health, eaten a moderate dinner, and gone to bed feeling comfortable; his mind clear and correct. In the night, sounds indicating dyspnœa attracted attention to his room, and he was found breathing stertorously in profound coma. In about two hours I saw him. His pulse and the action of his heart then, as before, told little. The coma was still complete, the pupils dilated, and little sensible to light; his skin generally warm. I had about eight ounces of blood taken by cupping, by which depletion his pulse sunk sufficiently to forbid its being carried further. Eight grains of calomel were laid upon his tongue, and sinapisms applied to his legs. A lavement also thrown up. No rally or improvement resulted. This was at 4 A. M.; he died at half-past 7.

In this case, I desisted from depletion at about the same point, as indicated by the pulse, at which it was suspended in Dr. Harrison and Mr. Allen's case. But I had no encouragement to resume it; and the cause of the disease, as well as the state of constitution apparently produced by it, contra-indicated the further prosecution of this measure.

No autopsy was permitted.

The phenomena of the following case belong more properly to my present subject, for though somewhat suddenly fatal it had not the strongly pronounced symptoms of apoplexia gravior, and yet was apparently of nervous origin. The subject of it was, up to his eighteenth year, a healthy well-grown young man, of a muscular frame, strong and active; until, indeed, he began to work at college with a view to a degree, having previously been far from laborious, but always of temperate habits. Then the peculiarities of his constitution developed themselves: a difficulty in giving continuous application, not from inability to fix his attention, but from intense exhaustion and a sense of fatigue produced. He struggled against this; grew thin, and, without any definite illness, faded. A year before the examination for his degree of B. A., I was consulted, and then learned and observed the above facts; and was much struck by the marked apprehension of mischief from his symptoms, in a bold, firm, and sensible young man. His pulse was small; the action of his heart normal. I gave him advice tending to prevent his fixing his attention too strongly on his discomforts, which I then presumed to be exaggerated,

and I prescribed tonics, mild aperients, and mercurials. His health improved in the above respects. In the autumn of 1840, I was sent for hastily into Berkshire to see him, where I found him under the following circumstances:—He had visited a friend sixty miles distant, and there, with moderate relative exertion, and with trifling deviations from a strict diet, had produced flatulent indigestion. Extreme exhaustion had suddenly come on, for which he had been treated reasonably by the practitioner of the place; and before he had quite recovered from this he had travelled home, by the high road. Finding himself still exhausted, he had, on the night of his arrival, taken twenty-five drops of laudanum. This increased his feeling of exhaustion. Palpitation of heart, a semidelirious state, and an intense feel of sinking, ensued. In the evening of the next day I saw him in Berkshire. He had by that time recovered out of the above exacerbation, and his only complaints then were a sense of soreness and stiffness in the head, of fluttering in the cardiac region, and pain at the epigastrium. His pulse 100, and small but regular. I found at the heart neither bruit, nor undue impulse, nor feebleness. A steady apprehension of death was marked in his own impressions respecting this attack. Out of this attack, however, he soon emerged into his usual health. The remedy which relieved him most (mild mercurials, and aperients being premised) was the ammoniated tincture of iron. During the next summer, a residence in the Isle of Wight, by my direction, with plentiful affusion of salt water, not the shower-bath, remarkably strengthened and improved him. He took his examination at the university after this, and thereby was relieved of a part of his mental difficulties. He continued, indeed, in an improved state of health, though one not differing in kind, till about eight months ago, when he received a shock which largely reproduced nervous sensations, in the death of a friend, and from that time to his own death it was observed that his wanness and pallor had increased. I believe he took for this the *tinctura ferri ammoniata*, without the precaution of previous mercurials and aperients. It was observed that he spoke very slowly, and that his thoughts, and apprehensions of the thoughts of others, were becoming more unready than before. He went down on a visit into Lincolnshire, and there he felt a return of increased exhaustion. One evening, complaining of this, he went to bed early; and not appearing at breakfast the next morning he was sought for, and found in a comatose and stertorous state, which had then not long existed, for we found he had been seen awake shortly before. Out of this comatose

state he did not rally, and he was dead in about three hours.

It is to be regretted, in the above two cases, that we have not post-mortem appearances. But in the present state of our pathology of the brain, the therapeutical question, in such cases, is not very closely connected with this inquiry. Neither tubercle, nor meningitis, nor cerebral abscess, are pointed to by the symptoms. The presence of some serous effusion is highly probable. But the nature of this phenomenon, as well as our uncertainty, in such cases, how long it may have existed before death, would make it difficult to obtain a practical conclusion from this fact, if discovered on dissection. The same remark applies to ramollissement. Under each of these suppositions the prolongation of life may be a point of immense importance; and under each, this object will, in the present state of our knowledge, be better gained at the bed-side than in the dead-house.

In the commencement of this lecture I adverted to the latter source of knowledge, as that which has given to practice its highest value and best effects; but its discoveries must not be anticipated or assumed. The researches of many eminent men have given to the treatment of thoracic and abdominal disease a basis in morbid anatomy. That epoch has not been arrived at generally in cerebral disease. Our scientific researches should continue to be aimed at this great object. But in the interim we must be contented to act, in a great degree, from more empirical resources.

With respect, then, to the treatment of the above case, the use of steel, preceded by mercurials and aperients, sea air, and affusion of cold sea water, appeared the most likely agents towards the prolongation of feeble life.

A question here may be allowed to suggest itself, why apoplexy should so often commence in sleep, when no stimulus is being applied. The fact seems explainable on the same grounds as the aggravation of dyspnoea under that state occasioning often a frightful waking up out of it, with embarrassment of the respiratory organs. Voluntary power is exerted, while we are awake, in obviating the derangement of these latter functions. Attitude is changed, expectoration is effected; we breathe in the manner and to the extent most suited to the condition and quantity of lung in use. Just so the state of assoupissement, towards which my last-mentioned patient was constantly tending, or frequently on the verge of it, had probably been a thousand times arrested by an act of thought; by the performance, perhaps, of some cerebral function rousing him before he had advanced into coma.

The following case may be admitted here, as affording a specimen of treatment, preventive it would appear, of nervous apoplexy or palsy, under a strong threatening of such states, occasioned by debilitating habits, indulged in during the youth of the patient, and admitted by him to me.

This gentleman, aged 37 years, was of the bilious temperament. He was short, well made, and had a compact sinewy figure. His eye was heavy; his countenance anxious and uneasy; his tongue red and smooth; his pulse irritable; his utterance slow and laborious. He did not exactly complain of want of strength, but he described himself as unable to walk more than a quarter of a mile at a time, from a sense of obstruction in his head, and pain and uneasiness in the loins. He spoke slowly, with evident circumspection, as if his articulation might fail him; and he collected his thoughts with difficulty. This gentleman has been relieved since that time, to the greatest degree, indeed his powers restored apparently, by a systematic use of the *spiritus ammoniæ succinatus*, mild aperients, and henbane, occasionally combined with mercurials.

There is a comatose state incident to infants, which is noticed in Dr. Gooch's admirable work on "The Diseases of Women," under the title of "some symptoms in children erroneously attributed to congestion of the brain." Some consideration of this state is allied to our present discussion; for the line is very delicately marked, and very important, which separates these cases from others requiring active depletion. I regret that I can give no more than an outline of a case which occurred to me before I had read Dr. Gooch's work, and places under the treatment and principles which he inculcates symptoms even more advanced into apparent congestion than those which he has mentioned.

An infant, aged eight months, and nursed by its mother, became feverish. The father gave to this infant two moderate doses of calomel and scammony, which appeared remarkably to depress its strength. Its motions, which had previously been healthy, became green; and having previously been plentiful, became scanty. Great debility was observed, and even paleness, a state not readily produced in infants. A full meal of its mother's milk was followed uniformly by griping and dyspnœa, threatening suffocation. The mother was a delicate person; but it was observed in the course of this case, that a more healthy nurse being obtained, the above symptoms were rather aggravated under similar circumstances than diminished. Small doses of castor oil removed the febrile heat which I have noticed, and restored healthiness of the evacuations; and this, with antispasmodics, was the only

medicinal treatment adopted by me throughout a continuance of symptoms, which, beginning in dulness and heaviness, ended in the most profound stupor, unattended, however, and unprecedented, by any indications of pain, heat of head, or convulsions. I was impressed with a belief that these symptoms depended upon indigestion and imperfect nutrition, probably resulting from the shock which ill-timed remedies had inflicted at the commencement of the indisposition; and I saw no ground for changing my view. When, however, after lasting several days, this case appeared to me desperate, it somewhat rapidly took a favourable turn. This change appeared to be mainly owing to the successful use of two remedies—one, the *spiritus ammoniæ succinatus*, given internally; the other, an *asafœtida* enema, thrown up about the same time. This, I imagine, was an infantile case of nervous apoplexy. With respect to the practice pursued, I shall regret if the successful termination of that case should exclude from the attention of my hearers the risk incurred, and the delicacy of that line, which separates such cases from others requiring the most active treatment, and often remedies of a depressing kind. A careful observation made of the exact point from which the attack, or those symptoms of it, have commenced, in regard to which the practical difficulty exists, will, in the present state of knowledge, give us more safety than a reference to any presumed diagnostics. In the above case, the shock given by the parent's injudicious remedies afforded this light to me.

With respect to nervous apoplexy considered as referrible to external influences, and not to constitutional causes, still of a physical kind, there are many forms of it. I should, indeed, vainly endeavour to embrace them in the course of a lecture. But they will generally, I believe, illustrate, with more or less concurrence, the proposition laid down in the present lecture, that the graver forms of nervous apoplexy require, strength permitting, the most active depletion; while its milder forms may best be dealt with by those soothing measures, and on those principles, which I have illustrated from the works of Dr. Kirkland. I have already pointed this out in regard to cases of insolation, classed under the head of apoplexia gravior. Let cases of this kind be compared with any given case, in which the extinction or diminution of power, and not its arrestation under spasm, may reasonably be supposed. The contrast will illustrate the difference of practice advocated, and vindicate its propriety. I will take, as an instance of such extinction or diminution of power, the exposure to an asphyxiating agent through the vapour of burning charcoal. If my

hearers will refer to the admirable case given by Dr. Babington, in the first volume of the *Medico-Chirurgical Transactions*, they will there find benefit derived, as might be expected, from certain excitants; but he will also notice a circumstance apposite to the present question, and the more valuable as it seems recorded under an expectation of an effect contrary to that which is admitted to have occurred. Twice the patient, a middle-aged man, lost blood in the course of his reanimation; each time his general state was obviously rendered less favourable by the loss. The latter removal of blood was accidental, from the displacement of a ligature. About this time it was noticed that reanimation was proceeding favourably; but under this accident, the face collapsed, and the pulse sank to a dangerous degree*.

In this case the vivifying principle of the blood having been interfered with, the directly restoring this by inhalation of oxygen gas, and the giving nervous energy for this work by galvanism, were the agents obviously and solely instrumental in the recovery.

OF THE

PATHOLOGY, DIAGNOSIS, & TREATMENT OF OPHTHALMIC AFFECTIONS.

By EDW. HOCKEN, M.D. M.R.C.S.L. &c.

[Continued from p. 276.]

A new and improved plan of treating strumous conjunctivitis. The pathology of struma. The nature and symptoms of the local affection, with the rationale of treatment.

Treatment.—This includes the treatment of the attack and the treatment of the interval, consisting of general and local treatment.

My friend Mr. Wormald is in the habit of treating many slight ophthalmic affections (especially among the out-patients of St. Bartholomew's Hos-

pital) exclusively by daubing the nitrate of silver on the outside of the lids. It was from watching the success of this practice in many cases that led me to give the remedy, applied in this way, a fair trial among my own private patients. I found that it was most successful in the forms of strumous conjunctivitis—so much so that, when combined with appropriate constitutional measures, it has never failed in my hands—and this not after the lapse of a protracted period, but, in recent cases, immediately; and, if chronic, after two or three applications. At the West of England Eye Infirmary strumous conjunctivitis is very common, and often most severe and intractable. At my request, Mr. De La Garde (one of the surgeons to that institution) placed several cases under this plan of treatment; and shortly after having commenced it, he wrote to inform me that, out of at least a dozen such cases, there was only one which was not immediately attended with the most marked success. Besides strumous conjunctivitis, I have found the nitrate of silver, applied in the way I shall immediately explain, a most valuable auxiliary in all cases where the conjunctiva and lids were much concerned, and wherever there was much intolerance of light; such as in all the strumous diseases of the eye, in catarrhal and purulent ophthalmia, in granular conjunctivitis, and simple conjunctivitis of the lids or globe.

Mode of application of the nitrate of silver*.—A clean piece of the stick of the nitrate of silver, having from one to two inches exposed, should be selected. The patient's eyelids are to be closed, and put slightly on the stretch, by applying the thumb of the left hand to the eyebrow, and gently raising the skin. The nitrate of silver is then to be passed (previously moistened) two or three times over the whole surface of the upper, and subsequently the lower eyelids, smoothly and without much pressure; bringing, not the point,

* Dr. Babington's expressions are as follow. "The pulse had risen to 120, and was strong (some wine and water given had apparently produced this effect); we therefore, in the early part of the evening, considered of the propriety of further venesection. But as the apoplectic stertor was evidently not so great, we determined not to interfere with the efforts of nature; accident, however, accomplished what we had hesitated to do, the ligature having slipped from his arm, and he lost, before it was noticed, nearly a pound of blood. The pulse sank, his countenance collapsed, and Mr. Hingeston was apprehensive that he would not survive the debilitating effect of this accidental hæmorrhage."

* The application of the nitrate of silver to the outside of the lids is a very different plan of proceeding to its introduction, either as a strong solution or in substance, between the lids. From the latter I have seen the greatest injury result, and should decidedly refuse my consent if myself the patient. Except in the purulent forms of conjunctivitis, it is a plan I utterly condemn, as cruel, injurious, and unscientific. Weak solutions, however (as j. or ij. grs. to the ʒj. of water) are sometimes highly beneficial.

but the sides of the stick of lunar caustic, in contact with the skin. The object of this application is only to blacken, and not to occasion any severer effects; and it will be found that, after a short time, as soon as the nitrate has had time fully to act on the fifth nerve, it will completely relieve the intolerance of light, the lachrymation, and, what is of the most importance, the spasmodic strivings of the orbicular muscle; and hence relieve the patient from that constant irritation and pressure which maintains and aggravates the affection.

In one of my patients, a little boy four years old, I had an opportunity of treating an attack of strumous conjunctivitis and purulent ophthalmia, in the opposite eyes, at short intervals of time. The strumous attack was subdued at once; but in about a week afterwards he was brought to me with purulent ophthalmia of the fellow organ. I at first used leeches, purging, and a strong solution of the nitrate of silver to be placed between the lids; but this treatment, although it subdued the severity of the attack, failed to cure it: it merely subsided into a chronic form. At this stage I applied the nitrate of silver to the outside of the lids, in the way described, which immediately gave a new feature to the case. He improved directly; and a second application, about a week subsequently, produced a cure in a few days.

On first seeing a case of strumous conjunctivitis, besides the application of the nitrate of silver to the outside of the lids, it is advisable to administer three or four grains of the hydrargyrum cum cretâ, or two of calomel, with one, two, or only half a grain of quinine (according to the age, &c. of the child); and follow it up, about six hours afterwards, with an appropriate dose of rhubarb, ginger, and sulphate of potash. If the smaller powder be given at night, the aperient should be delayed till next morning. Where the case is chronic, it is very serviceable to repeat this practice about twice every week or eight days; and where the child voids worms, it is best to free the intestinal canal from the nuisance by an appropriate plan of treatment.

It is not, however, sufficient merely to free the patient from ophthalmic disease for the time; the constitution must be improved, to prevent future attacks; and to accomplish this we

must strike at the root of the disorder. The general symptoms are those of debility—either a pale, pasty, bloodless condition, with flabbiness and want of tone in the solids; or, on the contrary, constitutional debility, with an excess of irritability of the nervous and vascular systems, occasioning a tendency to hectic. Both states are benefited by tonics. To improve the digestive and assimilative functions, we have recourse to hygienic and therapeutic agents. The former include diet, air, exercise, light, and clothing; the latter, tonics, purgatives, warm baths, or cold spongings, followed by brisk friction of the skin.

The diet should be nutritious, in moderate quantity, and taken at regular intervals, being well masticated; whilst every injurious or indigestible article should be studiously avoided,—such as pastry, new bread in every form, sweetmeats, crude vegetables, fruit, unless soft, fully ripe, and in small quantities, as strawberries, &c. Early hours should be enforced, both for retiring to rest and rising in the morning. A healthy situation (when possible) should be selected, with an occasional change of air, and a residence near the sea during summer. Sufficient exercise is very important; such as riding, walking, playing, &c. all in their turns; but fatigue is carefully to be avoided. The mind, also, should be kept employed, but never overworked. The body is sure to become diseased if deprived of the agency of sufficient light: hence the clear light of day and the bright sunshine must be sought and enjoyed. Exercise in the green fields combines the enjoyment of mind and body, exposure to light, a free supply of fresh air, and the stimulus of exertion. Moreover it is highly necessary to clothe the body warmly, both to encourage the functions of the skin, retain a due supply of warmth, and prevent the effects of atmospheric vicissitudes.

As purgatives, the combination of a mercurial preparation with quinine, followed by rhubarb, &c. as I have already mentioned, is the best mode of occasionally stimulating and strengthening the chylopoietic functions. Besides this, if the child be pale, and the solids deficient in tone, the ammonio-citrate of iron, in small doses, two or three times a day, should be adminis-

tered; but if the circulation be active, and the nervous system irritable, quinine, exhibited in the same manner, has succeeded best in my hands. In these latter patients cold sponging of the various parts of the entire cutaneous system successively, followed by brisk friction, I have seen most beneficial: in the former, where the skin is dry and rough, warm bathing, about once a week, also succeeded by active rubbing with a coarse towel or the flesh brush. This is but a sketch of the constitutional treatment; but having already filled several pages, I must bring these remarks to a conclusion.

If any gentleman will be kind enough to give my plan a fair trial, and report their success to me, I should feel much obliged.

Covent Garden.

RUPTURE OF AN OVARIAN SAC.

To the Editor of the Medical Gazette.

SIR,

THE accompanying cases appear to me very interesting: if you should entertain a similar opinion, you will oblige me by giving them a place in your journal.

I am, sir,

Your obedient servant,

ARTHUR W. DOMVILLE,
Surgeon to the Ardwick and Ancoats Dispensary,
22, Higher Ardwick, Manchester.

Nov. 12, 1842.

Case of rupture, from a full, of an ovarian sac, followed by death.

Sarah Wolstencroft, æt. 63, or thereabout, unmarried, always delicate, even from a child. Since the catamenia first appeared, there has been great irregularity in these discharges, and never, perhaps, has the secretion been of its proper quantity or colour. Thirty years since she first began to swell in the abdomen; this swelling did not increase rapidly, but, on the contrary, it very slowly advanced; but still it did advance, and at the expiration of fifteen years her abdomen had attained a large size.

It is now fifteen years since the operation of paracentesis abdominis was first performed, at which time thirty-four quarts were removed. She has been tapped four times since. The last operation was performed four years

ago, when a great quantity of little bodies resembling mustard-seeds came away; in fact, they were so numerous as to choke the canula and prevent the flow of the liquid part.

I believe Mr. Garside, of this town, performed all the operations.

Sept. 16th, 1842.—As this poor woman was employed in hanging window-blinds, the table on which she stood gave way, and she fell on her back on the floor. This happened at 10 o'clock A.M. I saw her about an hour after the accident; she was pale and sick, vomiting repeatedly, and complained of an agonizing pain above the umbilicus. Her pulse was quick and small. I prescribed stimulants; she had opium, brandy, and ammonia. She died at 5 o'clock P.M. Previous to her death she vomited a quantity of blood.

Autopsy.—September 17th I examined the body 28 hours after death. On opening the abdomen, I found that I at once came into the interior of an immense cyst, the anterior wall of which was inseparably connected with the abdominal parietes. The cyst passed down into the lumbar regions covering and connected to the kidneys; it was reflected from the abdominal parietes above to the under surface of the liver, with which it was intimately joined; in fact it required some time and trouble to bring this viscus into view, so completely was it covered by this part of the cyst. The posterior wall had various attachments with different convolutions of intestines, by cellular bands resembling the false membranes found frequently in the chest.

The cyst contained a large quantity of liquid, in which were floating innumerable little bodies, such as I have before described as resembling mustard seeds.

At the upper and posterior part of this sac there was a rupture, through which had passed two large folds of intestine (jejunum). The ruptured part corresponded with the seat of pain. There was a good deal of liquid extravasated into the abdominal cavity, also many of the floating little bodies before spoken of. There were no traces, however, of recent inflammation in any part of the abdominal viscera; the folds of jejunum within the cyst were distended with flatus, but there were no marks of increased vascularity; the

round shape was found occupying the whole lower and middle portions; extending, in fact, from the pubis to within two or three inches of the ensiform cartilage. It was composed of an immense number of cysts of all sizes: two or three large enough to contain three or four pints of fluid each; others not larger than a pea. The contents of the cysts were very various: in some the matter was colourless serum, in others it was yellow, in others as dark as coffee, and in others it was bloody. The consistency of the liquid was as varied as the colour. The walls of the cysts were of various thickness and structure; some were thin and soft, others thicker, and of a cartilaginous hardness; others vascular, and beginning in some places to soften and break down.

The anterior portion of the tumor was adherent, throughout its whole extent, to the peritoneum covering the abdominal parietes. It was also attached by a thick layer of soft lymph to the rectum, and on separating the attachment a small opening into one of the cysts was found. The cyst had ulcerated at this point, and formed an adhesion to the gut, which in time would, in all probability, have been perforated, and the contents of the sac evacuated. There were no other attachments to any of the intestines or viscera of the abdomen. The uterus and left ovary were healthy; the right was completely involved in the diseased structure, and was, no doubt, the organ in which the morbid action commenced.

Can we, in any given case, during life, predict the existence or non-existence of adhesions in ovarian dropsy? I firmly believe that this accuracy of diagnosis is, in many cases, most difficult of attainment; and in some it is quite impossible to determine.

We cannot ascertain this point from the size of the tumor, for we have seen that adhesions may occur at a very early period of the enlargement. We cannot judge from the amount of pain, with certainty; for in Wolstencroft's case the patient, I understand from her sister, never suffered so much pain as to require the use of leeches, and yet most extensive adhesions were found. In my second case the patient had suffered very great pain, and yet the tumor was free. And, lastly, we cannot always decide this question by

means of palpation or percussion: by the latter method we may possibly ascertain the boundary of the tumor, but can determine nothing as to its connections. Neither are we always much more successful by the former plan; for I have more than once known an ovarian tumor of some size appear to be fixed, which afterwards has proved to be free; and I can well conceive that an ovarian cyst may, to a certain extent, be moveable, yet nevertheless have contracted important adhesions.

The third feature in Wolstencroft's case, worthy of a passing comment, is the difficulty there was in making a diagnosis: I do not mean as to the connections of the cyst, but as to its real character. As far as the physical signs went, the case was more like ascites than ovarian dropsy. In no point of the abdomen could any solid enlargement be detected. The fluid was equally diffused; therefore, percussion where you would, there was nothing but dulness. By connecting the signs with the history of the case, we might, perhaps, have arrived at a shrewd guess as to its nature; but the diagnosis would have showed no better name than the one I have given it—a guess.

My object in making the foregoing observations is not wholly to deprecate the operation of excision; for I think that, in some cases, a surgeon may be called upon to undertake that operation. In fact, I proposed it to one of the patients I have already alluded to, in whom I found the operation free after death. Neither my patient nor her friends would consent; she was influenced by the opinion of my medical associate, who was far from sanguine as to the result.

I submit that this operation, perhaps beyond all others, requires consideration. I should not think a surgeon warranted in undertaking it because he had made the accurate diagnosis of ovarian disease; neither should I think him justified in its performance, even when he had ascertained, as far as it could be ascertained by palpation and an inquiry into the previous history, that the tumor had not contracted important adhesions. He ought, I submit, to satisfy himself that the case will be a rapid one, shortly terminating in death if something be not done to prevent such a catastrophe. Our object should be to save life, and not simply

to remove a deformity. The most sanguine advocates for excision must admit that there are many risks attending the operation. Could a man in justice jeopardise the life of his patient, by performing a formidable operation, when that patient, without it, might have lived, as mine did, for thirty years? I trow not. I readily admit that mine was a singular case; and that few, very few, are so slow in their progress as the one I have recorded; but still there are many cases that advance but tardily. If, in any given instance, we are satisfied that the case will rapidly proceed, and there are no strong reasons for believing in the existence of extensive adhesions, then our way is open: we may propose the operation, stating the risks; then leave our patient to decide.

ON THE TREATMENT OF APOPLEXY.

To the Editor of the Medical Gazette.

SIR,

I HAVE just finished the perusal of Mr. Chapman's cases and observations on the treatment of apoplexy, and on the employment of emetics in this disease, and as the subject is one of grave importance, perhaps the following brief remarks may not be altogether devoid of interest. My attention was early drawn to the treatment of apoplexy, in consequence of my paternal grandfather (the late Lieut.-Gen. Lewis) having died of the disease. At the age of 86, about 7 P. M. on the evening of his death, he was irritated at the conduct of one of his servants, and he immediately fell down, being seized with profound sopor. His countenance became pale; his breathing stertorous; the mouth was drawn to one side; the pupils were dilated, and his pulse was weak. He was quickly seen by a physician and surgeon; blood-letting was performed, and cold water poured over his head, but he expired in a few minutes.

On the 10th of June, 1839, I was hastily summoned to attend my maternal grandmother, and, on my arrival, I found her threatened with apoplexy. Her face was pale; the pulse was feeble; and she complained of vertigo and sickness. Her mother and sister

both died suddenly of this malady. She was ordered—

R Zinci Sulphat. ℥j.; Aquæ. Destillata fʒxii.; Fiat haustus statim capiendus.

In about twenty minutes vomiting ensued, and as soon as it had ceased she took—

R Pulv. Jalapæ. gr. xvi.; Potassæ. Tart. ʒii. Spirit. Ammon. Aromat. fʒss.; Infus. Sennæ Comp. fʒvi.; Aq. Pimentæ, fʒvi.; Fiat haustus.

This produced free purging; the vertigo diminished, and at 8 P.M. she fell asleep, and rose quite well on the following morning. Since this period she has had four similar attacks, and in all of them the above-mentioned treatment has been adopted with the same good result.

I have seen numerous cases of this description, both at home and abroad, and I have invariably pursued this mode of treatment, except that, in some instances, blisters or cupping were employed. On the other hand, candour obliges me to state, that in those cases in which the skin was hot, the face flushed, the breathing sonorous, and the pulse full and strong, I have witnessed the best effects from bleeding, croton oil, enema alôes, spirit lotion to the head, and mustard sinapisms to the feet.

Dr. M. Hall (Principles of Medicine, p. 256, 1837) asserts that there is great tolerance of loss of blood in mere cerebral congestion, while in cases of actual rupture he says the system is dangerously susceptible of its loss. He confirms the diagnosis to be frequently difficult, although he mentions the so-called distinctive symptoms. Abercrombie advises bleeding in all cases, for, in his admirable work on Diseases of the Brain, &c., he says, "there are no symptoms which characterise a distinct class of apoplectic affections which, in their nature, do not admit of blood-letting." And it is not to be denied that the profession, as a body, is thoroughly imbued with his views. It appears to me that the whole subject requires to be investigated anew.

I am, sir,

Your obedient servant,

T. C. LEWIS,

House-Surgeon to Wolverhampton Dispensary
and Casualty Hospital.

MEDICAL GAZETTE.

Friday, November 25, 1842.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
 publicum sit, dicendi periculum non recuso."

CICERO.

SANITARY STATE OF BRITISH TOWNS.

WHEN we look at those pictures of life as it might be, which are drawn by poets and moralists, and life as it is, drawn by Union surgeons and relieving officers, nothing is more striking than the contrast between the delineations of decent poverty, clean though patched, given by the former, and the squalid indigence represented by the latter. Yet each picture may be true; for, like the knights in the story, the controversialists are looking at opposite sides of the shield. Great, indeed, is the difference between the poor of the poet, who

"lived in a cottage far retired,
 Among the windings of a woody vale;
 By solitude and deep surrounding shades,
 But more by bashful modesty concealed;"

and the poor of Whitechapel, as described by Mr. John Liddle, in the Report on which we commented four weeks ago*.

Yet, as both these varieties of poverty exist, the question naturally springs up, what are the obstacles which prevent the one from rising to the level of the other?

In the first place, then, in many or most towns there is a deficiency of water to an extent scarcely credible. Even in London there are districts which are wretchedly supplied. In Whitechapel, water is not laid on to the houses occupied by the labouring classes, but they fetch it from a plug in the courts. The trouble of doing

this makes water scarce in their dwellings; and in consequence, the filth of the Whitechapel poor reminds one rather of some mediæval city, the constant prey of plague and dysentery, than of the metropolis of the world in the nineteenth century.

"When I have occasion to visit their rooms," says Mr. J. Liddle, "I find they have only a very scanty supply of water in their tubs. When they are washing, the smell of the dirt mixed with the soap is the most offensive of all the smells I have to encounter. They merely pass dirty linen through very dirty water. The smell of the linen itself, when so washed, is very offensive, and must have an injurious effect on the health of the occupants. The filth of their dwellings is excessive; so is their personal filth. When they attend my surgery, I am always obliged to have the door open. When I am coming down stairs from my parlour, I know at the distance of a flight of stories whether there are any poor patients in the surgery."

There is evidence also of the want of water in Manchester, the Truro Union, the Audley district of the Newcastle Union in Staffordshire, the Dunmow, Bishop's Stortford, Lexden, and Winstree, Unions; in Glasgow, Aberdeen, Stirling, Dundee, Greenock, Ayr, Arbroath, &c. &c.

In Edinburgh the poor have to travel a considerable distance for water, and afterwards carry it up five, six, or seven stair. In Tranent, Dr. S. Scott Alison has seen women fighting for water.

Even in Bath, which is comparatively well supplied with water, the poor are often obliged to fetch it from a distance. To the indolent this difficulty is an impossibility; even to the active it is a loss. In Paris, according to Mr. Chadwick, the cost of filtered water conveyed into houses by the carriers is two sous the pailful, or nine shillings a ton; while the highest price charged by the water companies in London is sixpence a ton. Such is the difference between individual and

* Report to Her Majesty's Principal Secretary of State for the Home Department, from the Poor Law Commissioners, on an inquiry into the sanitary condition of the labouring population of Great Britain; with appendices, &c.

combined labour; between rude manual exertion, and the machines of Savary and Watt!

It seems that the Poor Law Commissioners have been urgently requested to supply villages with water by allowing the necessary charges to be defrayed out of the poor-rates; "but they could only express their regret that the law gave them no power to allow such a mode of obtaining the benefit sought." At present the poor-law is potent only for ill: water gruel, but no water. *Ah! qu' il est difficile de faire le bien; il n'y a que le mal de facile à faire.*

The most striking instance of habitual non-washing to be met with in this Report, is at Edinburgh, where Mr. Chadwick talks of a question and answer more than once repeated: "When were you last washed?"—"When I was last in prison." So that recommitment to jail might be looked upon in these wynds as a blessing in disguise, being the sole or readiest portal to soap, water, and a towel!

The next difficulty experienced by the poor is that of obtaining *good* water; the supply may be plentiful, but bad. Indeed, this is a constant and just complaint in London, not only among the lower, but the middle classes; and the remedy will never be complete till the office of supplying the kingdom with water is taken out of the hands of private companies, and becomes a national concern, instead of the object of petty huckstering among rival dealers.

The effects of bad water are sometimes shown on a large scale. Thus the troops at Cork, being supplied with water mixed with the contents of sewers, and rendered brackish by the tide, suffered from dysentery: Mr. Bell, their surgeon, suspecting the cause, let water be fetched from the Lady's Well; *sublatâ causâ, tollitur effectus*—the dysentery disappeared.

At Paris, again, Parent-Duchâtelet ascertained that the proportion of sick at the prison of St. Lazarus was greater even than at other badly situated prisons. He found that the wooden cistern was in bad order, and full of *conservæ*, and that the water had a "detestable and truly repulsive taste." The water, moreover, of this hospital resembles that of the Salpêtrière in the quantity of sulphate of lime and purgative salts which it contains; and in the hospital, as well as the *hospice*, chronic diarrhœa is a prevalent disease.

Another point in which the poor as they are differ from the poor as they might be, is the bad ventilation of their places of work. The fact, that air to be wholesome must be renewed, is by no means universally diffused; and masters, not deficient in humanity, waste the lives of their workmen for want of a ventilation which might be procured by the profits of a week. "My people," says the Hebrew Prophet, "are destroyed for lack of knowledge." Place a plain scientific truth before a man, and spleen, distrust, nay avarice itself, in time give way; and physiology meets with almost as ready a reception as the multiplication table.

Mr. Thomas Brownlow, a tailor, aged 52, gives some interesting evidence on this topic, which is to be found in the Report. When a journeyman, he worked at Messrs. Allen's of Old Broad-street, with 80 or 100 men, and at the Stultzes, where the number was about 250. The men at Allen's sat nearly knee to knee: what with animal caloric, and the heat of the irons, the temperature was twenty or thirty degrees higher than that of the air outside; young men from the country fainted from the heat and closeness, and in the coldest winter nights large thick tallow candles melted and fell over from the heat.

The worse the air, the worse the habits of the men who work in it; depression calls for stimulus, and gin and

beer supply, in a destructive manner, the want of oxygen. Thus, in the shops of which Brownlow speaks, gin was brought in four times a day; at 7 and 11 in the morning, and at 3 and 5 in the afternoon.

In country places, where tailors work alone, or but two or three together, spirits and beer are far less drunk.

Besides the uneasy feverish state which must be produced by the alternate depression and exaltation of the London system, the journeyman is worn out ten years sooner; at forty he is older in constitution than the country workman is at fifty. In point of fact, the London tailor is superannuated at fifty years of age, and is thought unfit to do a day's work.

John Fowler, a superannuated tailor, who comments on Brownlow's evidence, agrees with him generally, but thinks that less beer and spirits are now consumed in the workshops, and observes that the crowding of the large shops occurs only during the season.

Charles Dobson, a man of 58, who has been a tailor since he was 16, has always lived in the country; yet even he has suffered from working with seven or eight men whom he employed, in a close shop. Though there was very little drinking, the men grew giddy, and in warm weather he felt faint, from the closeness, the stoves, and the hot irons. He has known many men, more than fifty years old, who are perfectly able to go on working; as they advance in age, they are obliged to give up, from defective sight, but from nothing else.

The remedy for these evils is an obvious one—ventilate the rooms. It is satisfactory to say that this has been done by the Stultzes, and also in some shops at Glasgow.

Milliners and dress-makers are equally injured by the defective ventilation of the crowded rooms in which they work; with the additional detri-

ment of the candles and gas-lights which glare over their midnight toils: for, while tailors usually leave their shops at 7 or 8, milliners slave on to an indefinite hour.

Nor are the sleeping-rooms of the working classes a bit better. In Aberdeen, according to Mr. Isaac Gilchrist, a surgeon of the town, six, eight, or ten persons not unfrequently occupy one room; and these are often single women, employed at the manufactories during the day, and huddled together at night.

If any one wishes, however, to know how closely human beings may be packed together, he should read Dr. Mitchell's account of a lodging-shop, as it is termed, for miners. In a room eighteen feet by fifteen, he found fourteen beds; one half being supported on posts, and placed exactly over the remaining half. Each of these beds was intended for two men, but when the mines are in full play, they are capable of receiving three men each, and, in case of need, a boy might lie across at their feet!

Dr. Mitchell says that 39 or 40 persons might have slept there; but it is obvious that, if his previous account is correct, 56 would be the possible limit. How even the smaller number can live through the night, is inexplicable. He thinks, with great probability, that these lodging-houses are more destructive than the air of the mines. William Eddy, a miner, gives an account of one of these crowded sties, in which he was wont to lie. Dr. Mitchell's supposition was realized there, for a bed often contained three of these human swine, besides one at the foot. "The breathing at night, when all were in bed, was dreadful."

Miners are worn out soon after forty years of age; but how much of this premature decay is to be attributed to the lodging-shops, and how much to work in the mines, it is not for

physician nor physiologist to determine.

It is clear that all the evil influences which we have disussed in the present article admit of remedies; either from private benevolence or legislative enactment. When the cholera spread terror among the opulent classes, the dwellings of the indigent were purified by force; could not this be done to avert diseases, which, though less suddenly sweeping, are more permanently destructive? The poor, said a philanthropist, are the children of the state; and it might be expedient, in some cases, to treat them like children, and guide them, when they cannot be taught. Still more necessary is it to set bounds to the cupidity of masters and landlords, and prevent them from coining blood for drachmas.

CLINICAL LECTURES,

Delivered at St. Thomas's Hospital,

By FREDERICK TYRRELL, Esq.

Surgeon and Lecturer on Clinical Surgery, at St. Thomas's Hospital School.

LECTURE II.

On Feigned Diseases.

IN a former lecture allusion was cursorily made to the general laws in which the student should seek for guidance in determining the character of any presenting case, or, in more professional phraseology, in the formation of diagnosis. Since, however, these laws are weakened by numerous exceptions, and beset by many ambiguities when practically applied, it becomes desirable, before explaining the best method of collectively surveying the particulars of a case, or *taking* a case, to attempt the removal of some of these perplexities, by indicating the avenues through which, in varied and subtle forms, imposition, fallacy, and error, may stigmatize reputation, and contaminate the conclusions of the mind. If all young practitioners were to proceed on the plan of estimating every example of disease, whatever its phaze or grade of intensity, as a separate essence or entity, characterized invariably and necessarily by an assemblage of definite particulars or phenomena, like a figure in geometry, or an experiment in chemistry, no instance would occur in which a manufactured story of subjective incidents

could usurp the place of facts and real occurrences. There is nothing imaginary or extravagant in the belief, that, even with the knowledge which may be rightly viewed as at present well understood and firmly established in medical science, it is quite possible for the student, within the period ordinarily allotted to his education, so to arm his mind with practical learning, and improve his capacity of observation, as to elevate himself into near approach to this supposed standard, before the commencement of those real scenes in which he is required to think and act for himself. Against the practicability of attaining this position, it may be urged, as an apparently valid objection, that, in the living organism, like causes are not always attended with like sequences; phenomena which may be symptoms of one state may equally characterize another condition of disease, both apparently similar, but in reality distinguished by essential and important differences. How, therefore, is the student to direct his course in safety between these manifold dangers of false diagnosis, and the unhappy consequences of a misconceived and misdirected treatment? But the fact is, that, notwithstanding all that we have said of the uncertainties of medical practice, the obscurity which overhangs the action of remedies, and the multiplicity of conditions which the correct application of any, the simplest remedy, involves, there are landmarks in the true philosophy of diagnosis which guide the observant mind to conclusions of great exactness. In the preceding lecture this subject was exemplified by two cases of ulcer of the leg, both strikingly similar as regarded external characters, but of which one owed its appearance to irritation acting on, and confined to the part, while the other was equally dependent upon causes of disturbance operating through the channel of the general system. If, then, it be quite practicable to discriminate between such cases, whatever the gradations of intensity or difference under which they occur, it is certain that, in every instance, the practitioner may place himself on a clear and intelligible vantage ground from which to direct the scheme of treatment. It is this accurate recognition of the conditions of disease that should engage the aspiration of every scientific practitioner. This is the eminence to which experience exalts the veteran in the warfare of actual practice. But the most fertile and frequent source of difficulty, in the prompt and certain recognition of disease, which harasses the old and experienced, as much as it discourages and perplexes the junior practitioner, is unquestionably referrible to the circumstance, that diseases seldom or never occur in a separate and isolated state. The conditions, upon the presence of which one may depend, may

be so closely interwoven with those of another, that the resulting symptoms may assume a compound or mean character, which, distinctive of neither, yet belonging to each, may conduct to very erroneous inferences of diagnosis. In the succeeding lectures it will be my duty to introduce you, as far as possible, into an acquaintance with those principles and tact which unobservant experience would consume many years in accumulating.

I have thought it desirable to offer here a few general observations, before proceeding more immediately to the business of the present lecture—that, namely, of considering the several sources from which fallacious and inaccurate evidence may obstruct the formation of correct judgment or sound diagnosis in the ordinary examination of disease.

There are instances, by no means infrequent in occurrence, in which persons affected with disease exercise a searching inquiry into all forms of books, without ceremony as to their antiquity or modernness, in which they are likely to be rewarded with an account of their case. They become thus philosophers in vain imagination, and soon assimilate their case to the portraiture of suffering which some favourite quack author may have fervidly and eloquently drawn. Thus impressed with a well and clearly conceived notion of their own distressing state, they approach the medical attendant with such a fluent and compactly modelled statement of their own infirmities, as to convince him that they positively labour under the disease the symptoms of which they so minutely and accurately enumerate.

Gentlemen, in such cases there is no designed imposture: a false impression is actually wrought upon the enfeebled imagination of the sufferer; and this disordered impression it is which moulds and animates his story. Fortify yourselves against the baneful errors into which a tale handled with such skill and dexterity would inevitably involve the incompetent and ill-informed practitioner; nor falsely impute to an innocent patient the intention or desire of decorating the history of his case with garbled and counterfeit incidents as unreal in occurrence as they are plausibly linked in the picture which he offers of his case: this were an error as unhappy as the other would be dangerous.

In periods of greater ignorance among medical practitioners than that in which we live, it was a circumstance which seldom happened that mere sympathetic signs and affections, which stand only in a remote and indirect relation to the real disease, were clearly and intelligently discriminated from the substantive seat and cause of distress. That painful sensation, having its apparent residence in the knee, which is so remarkably

constant in hip-diseases of scrofulous children, was oftentimes regarded, and positively treated, as a morbid action originating in, and confined to, the part itself; and no conception was ever formed of its dependence upon some other and remoter source of mischief—remoter, that is, from the sphere of careless, idle, and uninquisitive observation.

That annoying irritability and pain which so frequently affects the glans penis under circumstances of stone in the bladder, was, with equal error and discredit, ranged in the ill-selected category of *bona fide* disease.

You must not forget that the human body, whose mechanism is undoubtedly the subject of your daily study and admiration, and whose derangements you will soon discover will be the absorbing topics of your nightly reflections, is not an automatic compound of integral and independent elements, between which no communion or community, either of pleasure or of pain, subsists, like the complexly partitioned habitation of Alcyonidal Polyps, but is rather an organism whose component structures, alike remote and proximate, are united most wonderfully and intricately together by bonds of intimate sympathy. The universal prevalence of this sympathy renders it impossible that one organ or part in the general whole could submit to the ravages of disease without involving in a common disturbance the component systems of the body. These indications of sympathy are not unfrequently confusing obscurities between the mind and its arrival at correct conclusions in diagnosis. Take care lest you also fall under the condemnation which we have just pronounced upon the mistakes of our less tutored predecessors, and confound the secondary indications of sympathy with the primary realities of disease. But it is extremely important to understand that these remote pains of sympathy are not fictitious, or pretended for the ends of deception and gain: they are truly physical manifestations of disease. There is no class of diseases with which I am acquainted in which it is so important, in order to an accurate formation of diagnosis, to distinguish the actually local from the constitutional malady, as in that which is known as the *hysterical*. A part may be the seat of the most acute pain, and yet be in a state of perfect freedom from organic disease, but the vehement expressions which the patient may employ in the description of her suffering, when the finger approaches the affected part, may readily invite the unpractised observer of disease into a learned scheme of local treatment, as creditable to his honourable fame as it was advantageous and conducive to the welfare of his patient! I sincerely hope, and confidently believe, that it will never be said of any of you, who enjoy the fertile advantages for the cultivation of

medical study which this extensive institution affords, that he has mistaken the local sympathies of hysteria, however obscure their form or protean their character, for the signs of an actually existing disease.

But of all the numerous difficulties which are calculated to bring into discredit the judgment and character of a medical man, there is not one, that I have yet known, which is attended by circumstances of greater mortification than that in which a physician or surgeon is surreptitiously drawn into the position of mistaking the affected tale, the artful assumptions, and the adroit trickery of a designing impostor, for the expression of an actually felt pain, or the outbreak of real disease.

All men, as well in private as in public practice, are exposed to liabilities of imposition by persons who *feign* the character of disease. Those, however, who are engaged in the medical practice of public institutions, in the army or navy, or those who devote themselves to the medical attendance of clubs, or other large assemblies of individuals or families on the club system among the crowded population of mining and manufacturing districts, are more particularly those upon whom this species of imposture is most frequently practised. Since many of you whom I now have the pleasure to address may be ultimately carried into one or other of these several destinations which await the youthful members of our profession, our time will be found not to have been misspent if I present you with a few points, and recount to you a few of the many instances of attempted imposition and fraud which a long and active career of private and public engagements in my profession has brought within the sphere of my notice.

It was formerly observed that the majority of the phases and forms which disease assumes in the human subject is distinguishable by an assemblage of more or less clearly defined particulars. By all modern as well as antiquated authors in our science these are known as the pathognomonic signs of a disease. The presence or supervention of another disease whose signs may simulate the character, or present some resemblance to those indicative of the pre-existing affection, by introducing complication or obscurity into the picture afforded by the original marks, may obviously augment the difficulty of recognizing their character. But within certain limits, it may be repeated, that every practitioner, how young or inexperienced soever he may be, may supply himself with abundant means by which to obviate the unpleasantness which a judgment, as formally as it was, perhaps, falsely pronounced in regard to these cases of assumed diseases, will infallibly entail. The method of detection, in such cases, resolves itself

into two well-marked divisions; of which one may be described as a prompt tact and acuteness in discriminating the real from the fictitious, the exaggerated representation from the actual measure of suffering, the indisputable substance from the verbal shadow of the disease, which a long course of observant experience may ensure to the older practitioner; whilst the other may be emphatically denominated the method by scientific analysis. This last I introduce in terms of anxious recommendation, not on the score only that it is the best calculated to secure for you a safe exemption from the mortifying errors, and staining disgrace, into which the jugglery of an impostor may perchance entangle you, but rather on the higher ground of the direct tendency which it has of disciplining the mind into a logical and consecutive method of thinking, and of exercising its faculties of apprehension and reasoning on a plan, and in conformity with a process, which, of all others, is the most fitted to improve its powers, and teach it that precision of analysis which accuracy, either in determining the nature, or in estimating the combined value of any mass of evidence, under all circumstances, requires. For the purpose of illustration, let it be supposed that a case of an obscure nature is brought for examination, and that the surgeon reasons upon it in this way.

This person declares that he suffers under the disease A. From some of the symptoms which he describes, I am rather inclined to believe that the case is really one of the disease A. But there is an obstacle of a two-fold character which I feel I must surmount before I can with safety repose full confidence in this incipient belief; the first of which is, that the account which he has given me of the situation of the mischief, and the direction in which the sympathetic pains radiate, and the order of time in which the best indications which are usually said to mark the progress of the case have appeared, have not a sufficiently close correspondence with the account which the best authors have offered, or which my experience would induce me to believe as the most correct of this said disease A. The other is, that there are two other diseases, M and N, between which and the present case I could not confidently mark out any definite limit of distinction. Now the question is, to which of these three examples of disease, A, M, and N, does this case really belong, and if to neither, what alternative supposition is there left me? I suppose only that of believing that it is no case at all—unless, indeed, it be admitted as a very fine instance of humbug—for the old classic adage says, "*ex nihilo nil fit.*" Observe, I pray you, gentlemen, that suspicion at this stage of the examination puts forth her inquisitive whis-

pers; and the imposture is being arraigned before the tribunal of justice. The examiner proceeds and says:—Now from observation and reading I know that the disease A is invariably distinguished by the symptoms B, C, and D, and generally, also, E and F; but according to this person's account, C and D, the most important symptoms, are really not mentioned or noticed; while E and F are portrayed in very extravagant language: but the most anomalous discrepancy of any is, that the sign B, which is said by every one to happen at the very earliest commencement of the disease, has positively, in this case, occurred at the end, almost, of the changes through which the disease has passed, even several days after E and F, which are remote but by no means necessary consequences.

But it is really very odd what this case can be. It might certainly be an obscure form of M; but then, other very important signs, G and H, ought to be present, and very prominent too; and B, which happened so late in this case, should have presented only in a very minor degree, and at a very different stage of its course. And it cannot be the disease N, for then C and D ought to have been very prominent; but they are here altogether absent. But there is one other consideration, which I view as a very serious one, against the history which this man has drawn of his case. The *character* of the symptoms which are present is very unlike that of the reality. He says that the pain in the symptom B is very acute, and aggravated considerably by the slightest pressure.

Now it ought orthodoxly to be, that the pain should be of an obtuse quality, and that relief rather than pain should be experienced on pressure. Then what judgment can I pronounce with respect to the nature of this case? There are numerous and unequivocal flaws in the chain of the evidence. There are contradictions of time and character in the reputed symptoms. There is, in fact, in the collective aspect of the case, an air of inversion and deceit, which excites my suspicion. Is it, or is it not, a case of imposture? or is it a defective image of disease, which a morbid imagination has incoherently attempted to produce? An instance in which considerable difficulty was felt in the establishment of diagnosis has been thus hypothetically pictured, with a view to illustrate, by the assistance of a direct example, that path of analytic inquiry which the mind pursues, in closely and seriously tracing out the weight and tendency of any present sum of particulars. It is that process which I earnestly recommend for your adoption and imitation in every case, however simple or clear its character. Think, in every instance, what are the legitimate

as contradistinguished from the spurious manifestations of disease, before closing the process of investigation; and the occurrence of error will be well guarded against.

Cases of feigned disease present the most numerous and diversified possible shades of form and character.

I recollect a case of a woman, many years since, in this hospital, who obtained admission for a sore on the breast, which was supposed to partake of a malignant character. But after some time it was found to assume very singular intermissions, which came on after the proposal of an operation for the removal of the breast. The proposal was founded upon the suspicion that the case was periodically aggravated by some artificial means, for it was always found that when the necessity for the operation was strongly pressed, the sore rapidly improved, but if overlooked for a short time it would again relapse into a very irritable and painful state.

The mystic fluctuations of this case were shortly afterwards explained by the discovery of a portion of Emp. Lyttæ in the adjacent cupboard; so that it became better or worse according to whether this irritating agent was applied or not. It was by no means difficult to understand the motive which prompted to imposture in this instance. Immediately that doubt or suspicion is raised in the examination of any case, let the question be at once settled whether there can be any strong motive in the person for the affectation of illness. If the motive be probable and evident, suspicion should be the more strongly entertained. In the example which has just been related, who could have doubted that the thoughts of the lady were ardently set upon the luxuries of a comfortable bed, the cleanliness of a well ventilated apartment, the exemption from care and labour, which the liberal charity of an hospital conferred—in fact, the bliss of idleness?

In regard to the locality which this case should occupy in the nosology of feigned disease, it may be correctly enough classified under that genus of imposture which may be called deceit by aggravation, for the sore here *originated* without the concurrence of the woman, but was subsequently *aggravated* by the fraudulent and intentional application of irritating substances. The case therefore was not feigned. But the following is a remarkable instance of a disease, artificial and ingeniously produced, to accomplish the object of deception.

A butcher, who although himself attached to his country, cared little about its protection from the aggression of foes who may have threatened the annihilation of its peace and independence, began to tremble under the pangs of dreadful apprehension, when the levying company arrived to draft him for the ser-

vice of the Militia. In proportion, however, as his patriotism dissolved away into cowardice, his faculty of invention grew more active, and he became very anxious that his case should fall into that comfortable crevice, in the conscriptive law of our country, which excuses on the plea of corporal disability. "He reasoned by analogy, and thought, seasonably enough, of the process of inflating" the meat in preparation for the market: it accordingly occurred to him, that if he were to make a small and delicate aperture, somewhere in the vicinity of the loose integument of the scrotum, and blow into it, by means of a tobacco pipe, or some such instrument, it would have the effect of producing a very extraordinary appearance among the neighbouring parts; such indeed as to deceive the eye of the most expert surgeon.

The experiment succeeded, and he presented himself amid the groans and difficulties of progression. But the game was lost, for the nature of his prodigious scrotum was soon discerned, and the sweets of his civil life were soon exchanged for the glories of the military profession.

Here is another case, happening in my own private practice, which I was called upon to treat, with all the gravity and anxiety which the afflicted tenderness and wounded love of parental feeling could possibly infuse. A young lady, in the most comfortable and opulent circumstances, became the subject of sore leg, and had been confined to her bed for a period of nearly eighteen months; and it was found by the numerous surgeons who had successively waited upon her, that nothing would succeed in permanently improving the ulcer, for which she had been so long confined. Perceiving nothing either in the condition of the part, or the state of the general health, which could be interpreted into an adequate reason or cause for such extreme unwillingness on the part of this said sore to get well, I immediately asked myself the question, what motive for deception can there possibly be in this case? This nice young lady surely could never think of preferring the tedium and sickening monotony of a bed-ridden life for the varied pleasures of home and society, which, if in health, without limits she might enjoy. By a little tender and inquisitive conversation at her bed-side, I afterwards prevailed upon her to give me a real and true history of her case. She now told me, that as her mamma, when she was able to walk and in health, *would* persist in making her walk with the nurse in Kensington Gardens every day, a species of exercise against which she had the strongest aversion, she was determined to keep herself in bed by sprinkling a few warm cinders occasionally over the sore. Who could have dreamt that the whims and

caprices of an over-indulged young lady could have been combined, by revengeful obstinacy, into an adequate motive for such a protracted course of self-inflicted punishment? Amid the anxieties of future practice you would all do well to remember the useful lesson which this case inculcates. Never forget that, frequently, there is very subtle *method* in the hysteric tricks of tender young ladies.

Some years since a remarkable case occurred in the hospital, in which the late Sir A. Cooper was consulted. A woman came in with an alleged tumor in the right iliac fossa, which, she said, was caused by the escape of a fœtus, by rupture of the uterus during labour, many years before; and she proposed to submit to an operation for its extraction, as she was much alarmed lest something serious should result in consequence of the severe suffering she experienced. Sir A. Cooper, even before I suggested to him the suspicions which my own examinations had generated, finding that he could not discover this tumor in the iliac fossa, which the woman described, taking the evidence furnished by the areolæ, the breasts, the rugous state of the abdominal integument, and with that penetrating acumen of diagnosis which his vast experience, his well-disciplined mind, and his energetic resolve to unveil the truth in all instances of doubt and obscurity, had enabled him to acquire, at once concluded that the case was one of imposition; and not, as some surgeons had supposed, one of extra-uterine foetation.

It is not possible, in some cases, to detect the motive for feigning, even when the imposition is detected, as the following case will show.

I was requested to see a young gentleman who, it was stated, had been suffering very severely from facute pain in the lower extremities, which was greatly augmented by pressure or motion of any kind: this had existed for seventeen months, and had resisted a great variety of treatment under various medical men. On seeing this patient, and examining the limb, I elicited a train of symptoms which did not indicate any disease which I had seen or heard of; but knowing that the boy (who had been adopted by an opulent uncle) had every indulgence and enjoyment, I did not at first suspect any imposition. On deliberate consideration, however, such suspicion arose; and on the next day I made a more extended inquiry and examination, which confirmed my suspicion; and I accordingly expressed my opinion to the uncle, who was at the moment excessively angry with me for entertaining the idea of the disease being feigned. It was decided that a further opinion should be sought for, and the most

experienced in the metropolis was obtained, which confirmed that which I had expressed; and I then desired to have an opportunity of exposing the imposition, about which the uncle was even then incredulous; but he agreed to promote any plan I thought requisite to elicit the truth. My plan consisted in apparent coincidence with the patient as to the existence of a severe and obstinate disease, on which, however, I decided that nothing but an operation of the most formidable kind could effect relief; and that I wished him, therefore, to be removed to the neighbourhood of St. Thomas's, where I could have the straps, table, strong men, &c. &c.: making a long detail of what would be required in so difficult and dangerous a case. I succeeded in frightening my patient as much as I wished; and, after some difficulty, yielded to his earnest and repeated solicitations to try some remedy previous to an operation. I pretended I would try a very powerful remedy, provided the uncle would himself administer it, as I could not trust it in the hands of a servant in consequence of the damage from an over dose. I stated, further, that if it did not operate beneficially in ten doses it must be abandoned. The medicine ordered was a little ammoniated tincture of valerian and some castor combined, three drops to be given in a table spoonful of distilled water every two hours; and about sixteen hours after I again saw the patient, walking comfortably about his room, free from pain, being the first time he had left his bed or couch for more than twelve months. He declared that the medicine had produced a most extraordinary sensation internally after the first two or three doses, from which time his pains, &c. had rapidly passed away. His uncle and myself were now perfectly satisfied of his having feigned; though, perhaps, some of the present professors of homoeopathy would not only insist upon the possibility of the cure by such a dose, but probably complain of its magnitude. We never could detect any motive for this imposition; for the boy deprived himself of all kinds of amusement, such as field sports, &c., of which he was very fond, and which his uncle's means and property afforded him unusual opportunities of enjoying.

I might thus long amuse, and I hope instruct you, gentlemen, by withdrawing from the accumulated stores of my own experience of the difficulties of medical practice, cases illustrative of the varied shades which imposition or fictitious disease may assume.

Those of you whose intention it is to engage in the medical department of the army or navy, should recollect that the class of malingerers or skulkers is numerous. They look forward to the comforts of retired and civil life. They affect illness in order to ob-

tain escape from the lash of apprehended or adjudged punishment.

If you should ever visit the land of slavery, think of the pardonable motives which may influence the wretched beings who yet groan under thralldom and tyranny of abject servitude. They desecrate the land, and contemplate the delights, of liberty. They resolve to purchase it, even at the expense of health. They consume the mud and filth beneath their feet; and thus consign themselves unto the more tolerable condition of sickness and bodily distress, in order to emancipate themselves from the mental degradation of slavery.

If you are destined for the civil practice of our profession, study the principles of social life—the character of the human mind—the springs of human action; recollect the compassion which poverty claims at your hands, and elevate yourselves into an acquaintance with the philosophy of real life; and you will qualify yourselves the more fully for the useful practice of that elevated profession within whose pale you will soon be received.

REPORT OF
AN EXAMINATION AND ANALYSIS
OF THE "AQUA CHALYBEATA"
OF MESSRS. BEWLEY AND EVANS,
Pharmaceutical Chemists, &c. Dublin.

By ANDREW URE, M.D.F.R.S.
Professor of Chemistry, and Analytical Chemist.

THIS water consists of citrate of iron, highly charged with carbonic acid gas, and rendered peculiarly palatable by means of a little aromatized syrup. Six fluid ounces of it are contained in each bottle, and these afford, on analysis, seven grains and nine-tenths of a grain of peroxide of iron, corresponding to thirteen and a half grains of citrate of iron, present in the bottle, when prepared. This organic salt is therefore in accordance, as to composition, with the latest researches of Liebig; as also with mine, published in the Philosophical Transactions for 1822. The atomic weight of citric acid, as it exists in the citrate of silver, is, according to the German chemist, 165 ($C_{12} H_{10} O_{11}$) taking the British atomic weights for carbon and oxygen: and since this acid is tribasic (in his view) it will combine with 3 atoms of peroxide of iron = $3 + 79 = 237$, now $237 : 165 :: 7.9 : 5.5$, as given above. By my experiments on citric acid (Philosophical Transactions), its atomic weight with one atom of water, as in the citrate of silver, is 57 to hydrogen 1, which combines with one atom of peroxide of iron = 79, to form 136 of the ferric citrate, being proportions differing little from the preced-

ing. This chalybeate water cannot change by carriage or keeping, as the oxide of iron is held combined by so strange an affinity as to resist separation by the most powerful decomposing agents, such as the succinate and benzoate of ammonia, even with ammonia in excess; means which precipitate oxide of iron from all its inorganic saline compounds.

The Aqua chalybeata contains no ammonia, for when heated with caustic potassa it affords no traces of the volatile alkali either by smell or by chemical reagents.

Two ounces of this water are an average dose, and contain 2 grains and $\frac{2}{3}$ of a grain of ferric oxide.

From the mildness of this preparation, and its chemical permanence, it promises to form the most efficacious of chalybeate medicines.

13, Charlotte-street, Bedford Square,
November 18, 1842.

EXAMINATION FOR HONOURS

AT APOTHECARIES' HALL.

To the Editor of the Medical Gazette.

SIR,

MAY I ask the favour of your insertion of the enclosed questions given by Dr. Copland to the students who presented themselves as candidates for honours in Materia Medica and Therapeutics at the Apothecaries' Hall on the 31st of October last, in your valuable periodical; and also the names of the successful candidates. By so doing you will render us an act of kindness and justice.

I am, sir,

Your obedient servant,

HENRY MARCH WEBB,
Exhibitor in Medicine of the London University.

Guy's Hospital, Nov. 21, 1842.

1. Describe the preparation of the Antimonii Potassio-tartras, and the chemical changes which take place in the process.

2. Give the uses of this preparation: mention the states of disease in which it is most beneficial; and the medicines with which it is most advantageously conjoined in order to secure its good effects.

3. Describe the preparation of the Potassii Iodidum, and the chemical changes which take place in the process,—also the adulterations of it, and the best means of detecting them.

4. Enumerate the several preparations of Iodine, officinal and others; and state the several conditions of disease in which they are serviceable, with their doses, and the most usual modes of combining and exhibiting them.

5. Enumerate those medicines which act

as expectorants; arrange them according to their modes of operation, and state what you know of their physiological effects.

6. To what states of pulmonary disease are the individual members of this class more especially appropriate.

7. Enumerate the medicines which act as diuretics, with their doses,—and mention their physiological operation, and the best modes of exhibiting and combining them so as to secure their full effects.

8. Enumerate the medicines which may be employed to produce an emmenagogue effect; notice what may be considered to be their modes of operation; and mention their doses and modes of exhibition.

The prizes were awarded as follows:—

Henry March Webb, Guy's Hospital, first prize; gold medal. R. W. Golding, Charing Cross Hospital, second prize; silver medal.

SECOND ANNUAL REPORT

OF THE

GLOUCESTERSHIRE MEDICAL AND SURGICAL ASSOCIATION.

To the Editor of the Medical Gazette.

SIR,

AT a numerous meeting of the Gloucestershire Medical and Surgical Association, held at the Bell Inn, Gloucester, on the 4th of October last, the report, of which I enclose you a copy, was adopted, and which I shall be obliged to you to publish in your journal.

I am, sir,

Your most obedient servant,

JOHN W. WILTON,
Secretary to the Association.

Gloucester, Nov. 21st, 1842.

Report.—In presenting the annual report of the proceedings of the Association, the Central Section observe, with pleasure, that the grounds of congratulation which last year existed have, in no degree, passed away; on the contrary, the spirit with which the affairs of the Association have proceeded has been productive of increased benefit, and affords a just stimulus for further exertion.

Amongst the primary objects of the Association are the public interests of the profession, and parliamentary legislation connected with it. The events of the past year leave little or no doubt that some legal measure, having an important influence on the profession, will soon be adopted; the necessity, therefore, for medical associations, to watch and protect our interests, has become more imperative on this account than at any previous period.

experienced in the best possible opportunity, which confirmed the intention and I then desisted to bring in a bill for the purpose of exposing the conduct of the medical profession, and memorialized the Secretary of the Association on the subject. The requirements of the profession were strongly but respectfully set forth. The opinion of the Association on the important subject of medical reform, and the want of efficient legal protection to its members, were fully embodied with the general matter of the memorial.

The grievances inflicted on the profession by the Poor Law Commissioners have been an unceasing object of consideration. The legislature has been petitioned, and the individual members of both Houses of Parliament connected with this county have been addressed by your Society on the subject. From some of these answers have been received, exhibiting an interest in the profession and its present affairs; and although it must be acknowledged that, on the whole, our representatives indicate a most unjust indifference to those questions relating to the medical profession, still these repeated applications must tend to awaken a more lively interest in our behalf, and produce that share of legislative consideration which has hitherto been denied us.

It is even now a matter of congratulation that the efforts made by associated bodies of medical men have been productive of very considerable success. In the report of last year sanguine hopes were expressed of a modification in the working of the Poor Law Bill: those hopes have not been disappointed: and it has been shewn that the persevering remonstrances of large and respectable bodies of men, such as constitute our medical associations, compel attention, even from the reluctant ear of political leaders and Poor Law Commissioners.

The formation, then, of medical associations, which is now taking place in all parts of the kingdom, is a circumstance which may well afford our Society the greatest satisfaction; and it is a further pleasure to observe, taking a most prominent part in their proceedings, the most distinguished men who adorn the respective branches of the profession, many of whom can have no possible self-interest in the questions they engage in, and whose only motive must be the advancement and welfare and dignity of the profession, and the benefit of the public depending on it.

Amongst the occurrences of the past year, and possessing a high interest to the Society, must be noticed the prosecution of a druggist in Cheltenham for illegally practising as an apothecary. Our Association held communications with the Apothecaries' Company on the subject, and furnished information which led to legal proceedings, and the

conviction of the offender. This important check to the encroachments on the profession is a satisfactory result of the interference and efforts of the Association, and has been extensively made known as a caution to others, and a preventive or check to the evil.

Although, by past exertion, so much has been accomplished, there must yet be no diminution of effort. The practices of the Poor Law Commissioners, as they relate to the profession, will require a constant and vigilant observance; without an effort to retain it, even that which has been conceded may be lost: but the prospect of a bill to regulate our profession, to be introduced by the government, is a most anxious and important event. There is little reason to believe that the bill will be satisfactory to the great body of medical practitioners, and, if otherwise, the only chance of preventing its objectionable provisions from becoming law will be by the early and active efforts of associated bodies like our own, and the individual efforts of our members amongst their respective parliamentary representatives.

In carrying out the objects of the Association, every attention has been paid to economy; and it is hoped that the Treasurer's statement will meet with approbation.

	£	s.	d.
The expenditure during the past two years has been	25	8	6
And the whole receipts during the same period	21	4	0

Leaving a balance due to the Treasurer of £4 4 6

To meet which, there are unpaid Subscriptions to the amount of £8. 8s.

When the small amount of the annual subscription of each member is remembered, and also that all the expenses of forming the Association are paid, this statement, with which the section conclude their report, may well be considered satisfactory.

October 4th, 1842.

BRITISH MEDICAL ASSOCIATION.

WE subjoin a communication which we have received from Mr. Leeson, in reference to a letter purporting to be from him, which was published in the *GAZETTE* of last week, but which he now informs us was not written by him. A proof had been sent to Finsbury Square; and on questioning the person who took it there, he states that Mr. Leeson, when he returned the packet, told him he was not the writer of the letter, but that whoever wrote it must have been well acquainted with his sentiments, and that he had no ob-

jection to its publication. Of this conversation, however, we never heard till after the receipt of the following letter; and we greatly regret that Mr. Leeson did not see the propriety of at once either writing to us, or stating his disavowal on the returned proof, instead of delaying to do so until after the publication of the spurious document.

— ED. GAZ.

To the Editor of the Medical Gazette.

SIR,

THERE is a letter in your journal of last week, signed "James Leeson," and dated from Finsbury Square, respecting the British Medical Association. I beg to say that I am not the author of that letter, neither have I the least knowledge of the person who is. My christian name is John, instead of James, as you will perceive by my signature. I should not have noticed the letter at all, if it were not dated from Finsbury Square; and as I am the only person there to whom it could refer, and having no desire for its paternity, I forthwith proceed to its disavowal; and I feel the more anxious to do so, because it contained expressions towards individuals which I consider to be most severe and unjustifiable.

I never attended but two of the meetings of the British Medical Association, and that was when the founder of it first advertised them, and began to beat up for recruits. The actors then were made up of a great many young men, who were hard strugglers in their professional pursuits, as a consequence of the want of that legitimate protection which they so justly require, and a small knot of outsiders, or seasoned malecontents, of the older corporations, whose only concern was how they could use the fire and enthusiasm of their young and unsuspecting colleagues as so many stepping-stones (which has been so often done before) to their cupidity and ambition. I readily saw how the thing was likely to be; that the young ones were already in the gripe of the old ones; that it would fail to do all the good which might be easily done under a better system of organization; and things being thus, I made my bow and vanished. Ever since, I have taken no interest in the affairs of the British Medical Association, and perhaps it had no great loss in my departure from it. I am convinced that, had other elements moved the operations of that body, different results would have followed; and until wealth, influence, character, and numbers, meet in combination, little good can be expected. I am satisfied that we are not such a republican body as to suppose that if the gentlemen who now call themselves our heads were to expose themselves to a popular election, that the most of them would be restored to their present position; and how much more ho-

nourable would that position be to them, than to remain, as they now are, the jealous objects of an angry profession.—I am, sir,

Your obedient servant,

JOHN LEESON.

MONOMANIA OPHTHALMICA.

By DR. WINTERNITZ.

A GENTLEMAN, forty-nine years old, was seized with gout in 1837, which he himself was inclined to attribute to cold applications made to an accidental swelling of the head. But the simultaneous appearance of an obstinate paronychia on his right middle finger, together with the decline of his strength, earthy complexion, and emaciation, left no doubt as to the constitutional nature of the affection. Late in the autumn of 1840 he made a journey to North Germany in an open carriage, by which exposure he suffered from rheumatism. The abdominal organs became disordered, and about the same time he suffered morally from anxiety. All these concurrent circumstances had the effect of developing the hypochondriac diathesis in the patient. The disease which forms the subject of this article began in July 1841. Dr. Winternitz found him in a state of the greatest uneasiness, complaining of a confusion of head. During the day, and while in the act of walking, he had frequent attacks of faintness, followed by general perspiration. He was sensible of a sudden spasmodic constriction of the right eye-ball, as if it were confined and pressed in the socket, accompanied by an actual twitching upward and downward of the upper eyelid. Objects appeared as if surrounded by a gauzy halo: the patient was unable to read, in consequence of the letters appearing to swim before him. Writing was less difficult, although he was continually apt to carry the pen beyond the paper. The eye itself, beyond a slightly diminished activity of the lachrymal gland, betrayed nothing morbid.

The author's opinion that the affection was of an hypochondriac or psychical origin was founded on the following circumstances. There were no objective symptoms; the patient's whole attention was engrossed by his disease, which he was disposed to consider by turns of a congestive, nervous, arthritico-metastatic, &c. origin; he sought eagerly the society and conversation of oculists; disconsolately anticipated the total loss of vision: the patient had, moreover, at a former period, suffered from hypochondria.

The therapeutic indication was to withdraw the patient, as it were, from himself, and to interrupt his habit of constantly thinking of his disease. This was effected

chiefly by means of a jaunt to Paris. Here the patient was advised to employ tepid camomile-flower baths, with cold water douches along the spine. Vertigo became of rarer occurrence; he gradually regained facility in reading and writing; and after three weeks' residence in Paris felt a strong desire to revisit his family, whom he reached in perfect health.—*Oesterreich. Medicinische Wochenschrift*; and *British and Foreign Review*.

NECROSIS OF THE OS CALCIS.

M. MALLESPIKE, who has examined a great many cases of necrosis of the os calcis in children, states that, although generally dependent on a constitutional cause, it remains a long while without affecting the other bones of the tarsus, and that, in general, the only operation needed is the extraction of the sequestrum, instead of the amputation of the leg. This latter operation, he says, is more frequently practised than need be, because the tumefaction of the cellular tissue, which is sometimes enormous, the situation of fistulous openings at a distance from the os calcis, and the lateral mobility of the foot (the result of the destruction of the os calcis, whereby the heel has lost all power of resistance), induce the practitioner to consider the disease more advanced and more extensive than it really is. He observes, further, that the absorption of the sequestrum takes place very rapidly, and that the new bone destined to supply the place of the diseased one is deposited in the first instance on a level with the insertion of the tendo Achillis, and at the point corresponding to the calcaneo-cuboid and astragalocalcanoid articulations. The articular cartilages are not destroyed, and generally continue intact a long while; the ligamentous apparatus is generally found friable, softened, and thickened; occasionally, appearances have presented as if nature were about to supply the place of the lost ligaments by a fresh apparatus.—*American Journal of Medical Sciences*.

ON ADULTERATIONS OF OPIUM.

AN Armenian, who arrived here from Syria some time ago, and who had directed his attention for many years to the poppy plantations, as also the methods of procuring opium, told me that the adulteration of opium most frequently met with was that effected by mixing the opium, whilst fresh and soft, with finely-bruised grapes from which the stones have been removed. He assured me that not a single mass of opium is exported from the East without having undergone this adulteration.

Another adulteration consists in bruising the exterior skin of the capsule and stalks

of the poppy, together with the white of eggs, in a stone mortar, and then adding this mixture in certain proportions to the opium.—*Annals of Chymistry and Practical Pharmacy*.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

By ROBERT LEE, M.D. F.R.S.

LECTURE VIII.

On the structure and functions of the membranes of the human ovum in the early months of pregnancy.

At the end of the second month, the human ovum is about the size of a hen's egg, and is then contained entirely within the cavity of the body of the uterus. On dividing the membranes, the *amnion* will be seen forming a much larger and stronger sac than at the end of the first month after conception, but still very transparent, and without blood-vessels or regular fibres. In some ova, before the eighth week, the amnion has increased so much that it fills the greater part or the whole of the cavity of the chorion; and the cellular tissue which had been situated between it and the chorion has partially or entirely disappeared. The amnion is much larger, and contains a far greater quantity of liquor amni, at this period, in some ova than in others of the same age. The amnion and chorion always form the sheath of the umbilical cord; and the umbilical arteries and vein, and duct of the *vesicula umbilicalis*, can be seen through the amnion and chorion passing along the cellular tissue of the cord. The arteries sometimes begin at this early age to turn round the vein, and the whole cord to be twisted round near the embryo. In the third month of pregnancy the amnion and chorion are usually closely united together through their

whole extent, and continue to enlarge at the same rate till the end of the ninth month.

The *vesicula umbilicalis*, in healthy ova, is nearly of the same size at the end of the second as it is at the end of the first month; but its duct is impervious, and can seldom be traced farther than the umbilicus of the embryo. The omphalo-mesenteric vessels, which consist of an artery and vein from the superior mesenteric artery and vein, are often seen accompanying the duct, and ramifying upon the vesicle. In many ova expelled in abortion, the *vesicula umbilicalis* has lost the appearance of a pyriform sac filled with fluid, and is a small, flat, solid, opaque body, firmly adherent to the outer surface of the amnion, near the insertion of the umbilical cord into the membranes. It is sometimes seen in this condition on the fetal surface of the placenta, after its expulsion in labour at the full period.

The membrane of the chorion is at this time uniformly thicker and stronger than the amnion, and no blood-vessels have ever been observed ramifying in it. Its inner surface is smooth, but the whole of its outer surface is covered with villi, which grow from it by slender roots, and spread out like the branches of a tree under the decidua, in which they are firmly imbedded. The villi are most luxuriant on that side of the chorion where the placenta exists, but they are always present also on the opposite side of the chorion, and are joined together at their extremities, so as to form a great reticular or cellular structure between the decidua and membrane of the chorion. The villi often terminate in irregular-shaped bulbous enlargements, and from their sides slender filaments pass off, to connect them together. The villi of the chorion do not run in pairs like blood-vessels, and no anatomist has ever succeeded in injecting them. They are not blood-vessels, though often called the shaggy vessels of the chorion.

Seen through a powerful microscope, they resemble nothing so much as a mass of small, smooth, convoluted foetal intestines; but they do not appear to be hollow. From the sides of the villi others arise by slender roots, which often suddenly enlarge, and terminate in blunt rounded extremities. Between the roots and branches of the villi there are large cells or spaces formed, which all freely communicate together, and also with the cells or interstices of the placenta, which at this period do not essentially differ from the cells of the chorion, and are always, in ova expelled in abortion, distended with fluid or coagulated maternal blood. If a blow-pipe be introduced into the cells of the chorion or placenta, the air passes all round the ovum, and fills these cells completely. Injections thrown into the cells of the chorion or placenta, if they do not contain much coagulated blood, likewise fill the whole of the space between the decidua and outer surface of the chorion. That it is maternal blood which fills the cells of the chorion and placenta in aborted ova, is evident from this fact, that where the embryo is not developed, I have repeatedly seen these cells full of blood. There is no specimen of the human ovum now before you, in which there is not more or less maternal blood seen coagulated in the cells of the chorion and placenta; and it is impossible the blood could have been forced into these by any artificial means. This blood, it will soon be seen, can only enter the cells of the placenta and chorion through the small tortuous arteries which are always observed in that portion of the decidua which covers the uterine surface of the placenta.

FIG. 1.

FIG. 1 represents, though very imperfectly, the appearances presented by the villi of the chorion at the end of the second month. *a* shews the situation of the placenta; *b* is the part which lay under the decidua reflexa, where the villi are beginning to disappear.

FIG. 2—*a* and *c*, the chorion where the villi have disappeared; *b*, the situation of the placenta, where the villi of the chorion have continued to grow.

FIG. 2.

FIG. 3.

FIG. 3.—Diagram representing one of the villi of the chorion arising by a single root.

At the end of the second month of pregnancy, the structure of the placenta is essentially the same as at the full period. It consists entirely of the ramifications of the two umbilical arteries and vein, covered on the uterine side by the decidua, and on the foetal surface by the amnion and chorion. But all the branches of the vessels of the umbilical cord in the placenta have an additional coat from the villi of the chorion. In what manner the umbilical vessels pass into the villi of the chorion to become invested with a layer of chorion it is impossible to explain, unless it be admitted that they are developed contemporaneously. Between the foetal vessels covered with chorion there are cells or interstices, precisely similar to those which are seen on the opposite side of the chorion, where the villi also form a great chain, or series of cells, which all freely communicate with those of the placenta. There being no septum between the cells of those villi of the chorion which form the placenta, and those which are destined to disappear in the fourth month on the other side of the ovum, if maternal blood enters the cells of the placenta it must fill all the cells of the chorion; and thus not only the villi of the placenta, but all the villi of the chorion, must be in contact with, or bathed in, the maternal blood.

Diagram from Wagner, representing the uterus with its contents in the seventh week of pregnancy.

The embryo, perfectly normal in its conformation, is enclosed in its amnion. Betwixt the amnion and chorion the umbilical vesicle is seen. The uterus, lined with the decidua, is laid open, and its parietes reflected so as to shew its contents. *a*, The os externum; *b b*, cervix uteri; *c c c c*, the uterus laid open by a crucial incision, and reflected in four flaps; *d d d*, decidua vera spread over the uterine surface; *g*, flocculi or villi of the chorion; *g 2*, internal aspect of the chorion; *h*, amnion; *i*, umbilical vesicle; *k*, umbilical cord; *l*, embryo; *a*, space for the tunica media, as it is termed, between the amnion and chorion. The embryo is depicted of its natural size, but the other parts represented are only two-thirds the size of nature.

The decidua is the outer membrane of the ovum, and covers it as completely as the shell does the hen's egg. That portion of it which covers the placenta is called the placental decidua. At the margin of the placenta this membrane separates into two distinct layers, which extend over the whole of that part of the ovum which is not covered by the placental decidua. The outer of these layers of decidua is called the decidua vera, or uterine decidua, the inner layer the decidua reflexa, and between these there is always a large cavity formed called the decidual cavity. At the edge or circumference of the placenta, the placental decidua

always divides into two distinct membranes, between which there is a large smooth cavity, the outer wall of which is formed by the uterine decidua, and the inner wall by the decidua reflexa. The outer surface of the uterine decidua adheres to the inner surface of the uterus, but the inner surface of the uterine decidua is smooth and free, like the pleura costalis. The outer surface of the decidua reflexa is also smooth and free, like the pleura pulmonalis, but its inner surface firmly adheres to the extremities of the villi of the chorion, as the pleura pulmonalis does to the substance of the lungs.

The outer membrane of the human ovum,

Sectional plan of the gravid uterus, from Wagner, in the third and fourth month.

b, the decidua vera; *c*₂, the decidua vera passing into the right fallopian tube: the cavity of the uterus is almost completely occupied by the ovum. *e*, *e*, points of the reflection of the decidua reflexa; in nature the united decidua: do not stop here, but pass over the whole uterine sur-

face of the placenta; *g*, supposed allantois; *h*, umbilical vesicle; *i*, annion; *k*, Chorion covered with the decidua reflexa; *d*, cavity of the decidua; *f*, decidua serotina, or placental decidua.

now called *membrana decidua*, was first accurately delineated by Dr. William Hunter in 1774. The different portions of this membrane, and the relations they bear to the uterus, placenta, and chorion, have been most faithfully represented in eleven figures contained in the two last plates of his *Anatomy of the Human Gravid Uterus*. In one of the references to these figures it is stated, that the decidua reflexa forms an external covering to that part of the chorion which is not in contact with the inner surface of the uterus, and which is turned over the chorion much in the same manner as the inner lamella of the pericardium is reflected to cover the outer surface of the heart. In Dr. Hunter's *Anatomical Description of the Human Gravid Uterus and its Contents*, published in 1794, the decidua, in the early months of pregnancy, is described as a soft,

tender, pulpy, vascular membrane, which lines the whole cavity of the fundus uteri, reaching to the beginning of the cervix, and passing a little way within the origin of the fallopian tubes. The inner surface of this membrane is smooth, but the outer surface has a prodigious number of little processes, or flocculi, shooting from it, which give it a very irregular appearance. Dr. Hunter describes the decidua reflexa as a membrane of considerable thickness, and of a yellow colour than the uterine decidua, or decidua vera. The ovum, he says, lies between a part of the decidua vera and the decidua reflexa, both of which unite into one membrane at the edge of the placenta, or the decidua vera divides at the edge of the placenta into two laminae, one of which passes between the placenta and inner surface of the uterus, and the other forms the decidua

reflexa which covers the outer surface of the chorion. Where the decidua reflexa is beginning to pass over the chorion, there is, at an early period of pregnancy, an angle formed between it and the decidua which lines the uterus; and here the decidua is often extremely thin, and perforated with small openings, so as to look like a piece of

lace. Though the decidua be allowed to be the outer membrane of the secundines, Dr. Hunter observes, yet, as it is really the internal lamella of the uterus, we may still retain the old language, and say that the outer membrane of the ovum is chorion, and that the chorion is in contact with and adheres to the uterus.

Diagrams from Dr. Hunter, to illustrate the membranes of the ovum.

FIG. 1.

FIG. 2.

FIG. 3.

Fig. 1, a vertical section of an ovum of about nine weeks. A A, the section of the placenta which is supposed to adhere to the upper and back part of the uterus; B B, the section of the anterior portion of the decidua; C C, the section of the posterior portion of the decidua; D, the termination of the decidua at the cervix uteri; E E, the cavity of the amnion, in which the embryo hangs by a slender navel-string, from the inside of the placenta; F, the section of the three membranes, which are not only contiguous, but adhere to one another, viz. the amnion, the chorion, and the decidua reflexa; G G, the angle at the edge of the placenta where the inner layer of the decidua is reflected over the outside of the chorion; H, here those three membranes are a little separated, to shew their course at the placenta.

Fig. 2, an aborted ovum about eight weeks. A small strap of the decidua has been cut out, and turned up, and the decidua opened by a crucial incision, and the four angles reflected, and then a round piece of the decidua reflexa dissected off, and turned to one side, to shew the villi of the chorion.

Dr. Hunter has said nothing respecting the physiology of the decidua reflexa and uterine decidua, or of the great cavity formed between them; and he has not endeavoured to explain why these structures should exist only in the human ovum during the early months of pregnancy. Though many distinguished anatomists have examined and described the different portions of the deciduous membranes during the last sixty-seven years, no important addition has been

A, the cut slip of decidua turned up; B, the part of the ovum where Dr. Hunter supposes there is no decidua, viz. opposite to the passage of the cervix uteri; C C C, the inside of the four angles or flaps into which the uterine decidua was reduced by a crucial incision; D D, the decidua reflexa covering the villi and cells of the chorion; E E, the angles at the edge of the placenta, where the uterine lamella of the decidua is continued over the outside of the chorion, forming the decidua reflexa; F, a round portion of the decidua reflexa dissected from the outside of the chorion, and turned aside; G, "the chorion with its shaggy vessels laid bare. These vessels adhered firmly to the decidua reflexa, and parts of them were cut off with that membrane."

Fig. 3. A diagram, not from nature, of an early ovum in the uterus. A A, uterine decidua; B, placental decidua; C, the cavity of the amnion; D, the cavity or space between the amnion and chorion; E, the cavity of the decidua; F F, the tubes open upon the inside of the decidua. The cervix uteri contained no part of the ovum.

made to Dr. Hunter's description of them; and the greatest discordance of opinion still prevails respecting their structure, functions, and mode of formation. Some have denied altogether the existence of the placental decidua and the decidua reflexa, and others the vascularity, and even the organization, of the uterine decidua. It is still the opinion of some anatomists, however destitute of truth, that the decidua is merely the altered mucous membrane of the uterus.

Fig. 1.

Fig. 1 represents an aborted ovum of five weeks described and figured by Wagner. The various parts of an ovum at this period are well seen, and all in their natural state, except the decidua reflexa.

FIG. 2.

Fig. 2 represents the same ovum in outline; *a*, indicates the decidua uteri reflected at *b*, into the decidua reflexa *c*, which is thickened by the infiltration of blood; *d*, the villa of the chorion; *e*, the amnion laid open; *f*, the reticular tissue of the amnion; *g*, the umbilical vesicle.

In the next lecture I shall state certain facts which seem to prove that the circulation of the maternal blood in the human ovum during the early months is entirely carried on by the different layers of the decidua, and by the cells of the placenta and chorion.

LUMLEIAN LECTURES,

Delivered at the Royal College of Physicians in London, 1842,

By T. MAYO, M.D. F.R.S

Physician to the Marylebone Infirmary.

LECTURE III.

On Hysteria.

The disease, properly so called, often confounded with hysterical diathesis: mischievous results of this. Illustrative cases. Criteria considered through which this confusion may be avoided. Illustrative cases.

THE line which separates apoplexy arising from vascular action from apoplexy depending on other influences, is analogous to that which is carried out with various degrees of precision, in various instances, between hysteria and inflammatory affections, or, generally, those affections which require depletory measures. I shall endeavour to point out some of the difficulties which attend upon diagnosis in these cases; then to suggest means for the removal of those difficulties.

It is very probable that the basis of vascular excitement is often laid in affections of the nervous system, however much this vascular excitement may react, and become itself a source of nervous affection. That there is a state of the nervous system in which vascular excitement is easily set up, and, it may be presumed, easily pacified, we have reason to believe, from its leading to no appreciable changes of structure in such cases. This holds good with what is called nervous disease generally; and it is extensively true with regard to phenomena occurring under the hysterical constitution.

But there is a specific disease recognized by nosologists, and pursuing a definite course, generally springing out of the hysterical constitution, but apparently capable, under strong exciting causes, of occurring without such predisposition. This is hysteria: and to all the phenomena of this disease, the remarks above made, as to the appropriateness of a treatment into which depletory measures must be admitted sparingly, if at all—to all phenomena, I say, of hysteria, these remarks are applicable.

But when the theory here suggested, so applicable to hysteria, is extended to the hysterical constitution, it is not equally safe, or productive of just views. Many symp-

toms, or groups of symptoms, arise and run their course in a hysterically disposed person, which certainly take some tinge, or colour, or shape, from the constitution of the patient, as every disease varies according to idiosyncrasy, but which are not without mischievous practical results treated as, or confounded with, the hysterical disease. This latter state has a treatment of its own, to which we have above adverted, specifically different from that of other diseases. But symptoms, or trains of symptoms, may spring up in a hysterical constitution belonging to nosological heads entirely distinct from hysteria: and these symptoms will demand that the general principles of treatment applicable to their proper nosological placing should be carried out: and this demand will not safely be superseded, though it may be modified in its stringency, by the hysterical character of the constitution in which we presume these symptoms to be occurring.

The following cases may at once illustrate this view, and prove its importance, or, at all events, its right to be considered.

When I first saw the young lady who is the subject of the present case, and who was a florid, well-grown person, aged 20, of the mixed nervous and sanguine temperament, she had, for some days, laboured under cerebral symptoms. Since the abridgment of her last period, in the preceding week, there had been increasing upon her acute pain in the head, on which delirium rapidly supervened, with daily rigors, and extreme intolerance of sight. This was her state when I saw her. She had been freely purged in the last three days; nothing further had been done. Her complaints of pain in the head were incessant at that time. I directed that her head should be cropped close—the hair being luxuriant,—evaporating lotions applied constantly, and three grains of calomel given every fourth hour. In forty-eight hours the evacuations had become green. No increase of symptoms had taken place, but no abatement of them, and her strength had fallen much.

Having observed some periodicity in her symptoms, and some other evidences of nervous affection, and trusting that the calomel had placed her in a state of safety in respect to the inflammatory or congestive part of the case, I now gave her sulph. quinæ, gr. ij. 4tis. for about six doses. On this her strength increased, and the shiverings ceased: the mind also became clear. And now set in a series of hysterical symptoms. Hiccup first took place, with severe spasms; soon opisthotonos and prosthotonos. These symptoms obtained relief from free doses of laudanum. On one of these, however, extreme depression of pulse ensued; and then a sudden and total inability to swallow took place,

with a marked sense of constriction in the larynx.

For a fortnight the obstinacy of this spasm was unabated, and no food or liquid was swallowed. Her mind meanwhile had become perfectly clear, and the most anxious efforts were made by her to overcome the difficulty. During another fortnight small quantities of ice, or vinegar and water, were occasionally taken. At the end of that time we succeeded in conquering the spasm by means of a tube attached to a common syringe with a curved extremity, the curve of which was carried behind the molar teeth, over the dorsum of the tongue, across the posterior fauces. It is to be observed, that she gave us the most ready and complete assistance towards the completion of this measure. Her will was certainly used in concurrence with us; but, unassisted by the instrument, it was powerless to help her. During this time the mind indeed was perfectly clear. Daily nutritive enemata were given, and much appeared to be retained. Broth was now freely injected into her stomach: the moment after a full expiration being always seized for this purpose. Once only she opposed this measure, her expression of countenance being at the same time wild and unreasonable. I then resorted to cold affusion: first dashing water into her face, then pouring it on her head. This instantly quieted, soothed, and pleased her; and she instantly took the food, though not with less difficulty than before. Meanwhile aperient enemata kept the bowels open; and the bladder never acting of itself, the catheter was used every twelfth hour. On this point, by the way, I must venture to appeal to a case published by Sir B. Brodie, in his work on Hysteria, against the strong disapprobation expressed by him in that work of the use of the catheter in hysteria.

"In a patient," he observes (p. 67), "who had long laboured under hysterical retention of urine, the bladder was found enormously distended, of a black colour, the mucous membrane being at the same time much attenuated."

My patient now improved, and convalesced very gradually. Since the head symptoms gave way she had constantly complained of much tenderness of abdomen. This continued long, and gradually left her; the only remedies used in relation to it being asafoetida and mildly aperient enemata. The symptom so frequent in hysteria shewed itself largely—that of immense faecal evacuations coming away as the spasmodic symptoms yielded. When waywardness occasionally shewed itself, provided there was sufficient heat of skin, we repeated the cold affusion. The whole attack finally subsided, but she long continued in a very weak state.

The above case was considered by myself

and Mr. Newington, who attended with me, as, at the commencement, meningitis. But we took into consideration the nervous diathesis of the patient, and trusted to active aperients, calomel, cold lotions, and a darkened room. When the fecal evacuations shewed that the calomel had affected the system, and nervous symptoms became prominent, we resorted partially to quinine, principally to antispasmodics and sedatives, assisted by enemas, cold affusion, and Mr. Newington's ingenious instrument for the introduction of food.

Had the above long train of symptoms been conducted on a view of the case which, recognizing the hysterical diathesis of the patient, would have anticipated the outbreak of hysteria itself, and treated the initiatory head symptoms as a part of an hysterical disease—that is, had antispasmodics and sedatives or tonics been instantly resorted to—how would this case have proceeded?

This question may, perhaps, be answered satisfactorily through another case, which I will proceed to communicate.

In the spring of 1840 I was consulted respecting a young lady, aged 15, whose previous symptoms, as detailed by her mother, and confirmed on other authority, are indeed calculated to illustrate this subject. She had grown rapidly, was of the nervous temperament, and predisposed to hysteria. At the commencement of June 1839, she is described by her mother as attacked by head symptoms, which an eminent practitioner at Leamington regarded as hysterical, and treated with a succession of remedies (excluding depletion) relatively to this view. This treatment was continued from the 14th to the 23d of June most unsuccessfully; and it would appear that the physician desponded as to the event. At this point of time the case was transferred to Mr. Prichard, of Leamington. Such was Mrs. M.'s statement to me.

Curious respecting this subject, which recalled to my mind the case last detailed, and some others which I had seen, I consulted the *MEDICAL GAZETTE*, where I was told I should find a communication from that gentleman. This letter from Mr. Prichard carries with it so much material for thought, in the distinction to be observed between hysteria and inflammatory action modified by the hysterical diathesis, that I will give it you in full, or nearly so. It is in fact scarcely susceptible of compression.

"The young lady," Mr. Prichard observes, "had complained on Friday, the 14th, of languor and debility, with slight headache. On Sunday these symptoms had assumed an important character: vomiting had occurred; pallor had given place to a flushed countenance: then came imperfect vision, squinting, convulsions. I will not advert to the treat-

ment adopted before I took charge of the case, further than to say that depletion had not been considered expedient, but I will describe the state of the patient at that time, Sunday the 23d. She was tossing her arms and body convulsively about the bed; her moans at the same time expressing severe pain. Her countenance death-like, cold and pale, except one flushed spot on the left cheek; a dark livid appearance, surrounded the eyes, which were open, fixed, and filmy, the sclerotic discovering a number of injected vessels. The pupils contracted, and insensible to light; the tongue protruded from the mouth, and firmly held by the teeth closed upon it; the extremities cold; the hands of a livid blue; no pulse perceptible at either wrist, but the carotids gave a thrilling frequent beat, and the head was extremely hot."

The practice adopted by Mr. Prichard, without giving any hopes of success, was the removal of a profusion of hair, and the use of cold lotions, with a view, he says, of mitigating the convulsive movements. The relief, he says, thus obtained was so great that he proceeded to further remedies. Thirty leeches were applied to the front and top of the head, which bled freely. In the evening, finding the extremities less cold, and the countenance less expressive of suffering, he applied more leeches to the temples. He was now enabled to get a little calomel into the mouth, which was swallowed; the jaw relaxed its hold on the tongue, and during the night the juice of some strawberries was swallowed with avidity. The tongue was moist and loaded; some sleep was obtained for a few minutes at a time. Subsultus, however, of the muscles of the arms was very observable.

Monday, 24th.—Bowels had acted freely, but involuntarily, as also the bladder; pulse perceptible, as a fine thread, at the wrist. Juice of strawberries was continued. Calomel, 6tis horis.

Tuesday.—After a better night, more consciousness; eyes still fixed and glassy, pupils contracted. She expressed in a low whisper she had pain in the forehead. Hirud. viij. temporibus; emp. lyttæ nuchæ; calomel, 6tis.

In this state, or one little varying, she continued till Friday the 28th; then a change took place for the worse. Extreme subsultus in arms and legs; pulse almost imperceptible, from 130 to 160; countenance expressive of great pain and suffering. In the evening violent convulsions, which continued with increasing force and decreasing intervals, exceeding in volume, but resembling in kind, the paroxysms of hydrophobia, with violent ejection of saliva.

The patient was conscious of, and violently frightened at, the approach of each spasm. The pupils were now dilated, and partially

sensible to light. The bowels and bladder acted involuntarily under the spasms.

Acting upon his hypothesis that the case was meningitis, and reasoning from the relief which had followed depletion a few days before, Mr. Prichard took four ounces of blood in a full stream. The artery soon afterwards bursting out afresh, eight ounces more were lost. The paroxysms then diminished in force, and soon entirely subsided. Some slight progress was daily made until the 9th of July, in the night of which the paroxysms returned with much force, accompanied by screaming. The bowels having been rather torpid, a dose of castor oil was given, and the attacks again disappeared on the relief produced by its operation. From this time the progress of the patient to recovery was uninterrupted by relapse. The sight being gradually restored, the eyes became acutely sensible to light. Food was taken, though with difficulty, owing to an aphthous state of the mouth. The bowels acted freely, and entire power over their action, as well as that of the bladder, was gradually resumed. Leeches were still occasionally applied, and the head wetted, from time to time, with a spirit lotion. In the course of the treatment, mercurial ointment, Mr. Prichard adds, had been rubbed into the head.

This case is termed by Mr. Prichard *meningitis*, and that it required treatment appropriate to that title, as conducted by him, is very evident; yet it exhibits many evidences of hysterical *diathesis*; and thence it happened, I presume, that the gentleman who had charge of the case before Mr. Prichard treated it as *hysteria*—a disorder for the management of which he enjoys high reputation.

The following case has for some years circulated through medical hands in London and Leamington, and many other places. It may at least “point a moral” and illustrate a principle, though far from satisfactory in regard to beneficial results to the patient herself.

By the age of 50, the lady who is the subject of this case had, in a remarkable degree, exhausted the energies of a very excitable constitution. She had been twice married. Her first marriage, during the brief continuance of it, had been one of pain and grief to her. Her mind and her body were worn by unavailing exertions and sympathies in watching over a sick husband. A state of leucorrhœa then commenced, which was aggravated by mismanagement of herself. In order to supply a new stimulus and object, and on a false conception of healthiness, she devoted herself to excessive bodily exercise, and under this came on severe pain in the loins and increase of leucorrhœa. Meanwhile, the insatiable curiosity of an

over-active and volatile mind was a continued drain upon nervous energy. Opulence gave her the fullest means of gratifying it; and finally the acquisition of rank, to which she was not born, had its vertiginous effect. She was withal a hearty eater, and full liver, though spare in person. Under these circumstances, it might be expected that the hysterical diathesis, if its elements existed in her constitution, should largely develop itself. We might expect attacks of hysterical flatulence, occasional and unexplained losses of nervous power, or intense excitement and exaggerated sensation; we might expect, also, irregular cardiac action, unsteady appetites and inclinations, and incessant changes of plans and physicians; and all this took place. But there were other symptoms which had been gradually advancing upon this lady. These were, spasmodic movements, with numbness and loss of power in the hand and right lower extremities; the first making writing difficult, the second preventing her from walking without assistance, and occasioning her to drag her leg; and there was tightness as of a cord drawn round the abdomen: and it is to be observed, that the more important of these symptoms were not transitory and fugitive, but permanent. I had, for some time, been attending this lady, and had materially benefited her in relation to some symptoms of dyspepsia. The intense pain of the spine, which she experienced at a fixed point about two hours after taking food, was relieved by dietetic expedients, *i. e.* by occasioning her to exchange solid animal food and green vegetables for softening and farinaceous food, and by mild aperients substituted for drastic doses. But now a consultation occurred between Sir Astley Cooper, Mr. Hale Thompson, and myself. Tenderness was found on gentle percussion being made on the spinous processes of some dorsal vertebrae, which tenderness had escaped attention on an examination made by former surgeons; and recumbency, with the application of moxas, was recommended. The advantage gained on this plan at first, in its subduing pain and obviating flatulent indigestion, was very great. But the stimulus of novelty, and the pleasure which a *bearable* degree even of pain gave to one whose love of excitement and novelty was immoderate, soon wore off. The patient became tired, restless, careless in her diet, and generally unobservant of rules: indeed, the facility of digestion which the counter-irritants gave her enabled her to transgress dietetic rules with less immediately inconvenient consequences. Of course the plan failed, spoilt by the patient.

About a year after this period I inquired of an eminent physician then attending this lady how she was, and found that the view of her case, which assumed the existence of

an inflammatory spinal affection, independent of hysteria, had been given up entirely, and that her case was considered as falling under the head of that class of disorders for which the term hysterical spine has occasionally been used. Discomfort was mitigated, as it had been before, by attention to the digestive organs; frequent change of place relieved and interested her mind, and withdrew her attention from her grievances; but the paralysis remained the same and unchanged. Indeed, I have competent grounds for asserting that this class of symptoms has increased*. Now I do not undertake the defence or assertion of the practice which we adopted for the relief of the presumed inflammatory spinal symptoms; neither do I, at present, vindicate the diagnosis of Sir A. Cooper, Mr. Hale Thompson, and myself, which resolved them into meningeal inflammation and subsequent effusion into the theca vertebralis; but I feel justified in asserting that those definitions, on the right observance of which mutual understanding, correctness, and consistency of practice, must depend, are mischievously relaxed when the above phenomena of paralysis are viewed as phenomena of hysteria.

Similar doubts may, I apprehend, be entertained as to the designation of the following case, classed by Sir Benjamin Brodie under the head of "various forms of local hysterical affections." "I was consulted," he observes, "concerning a young lady who complained of severe pain, and morbid tenderness of the knee, in the first instance, attended by no perceptible enlargement of the joint. The remedies which, with such knowledge as I then possessed, I was led to recommend, gave her no relief, and after some time a slight degree of tumefaction took place, depending, as it seemed, either on a fulness of the small vessels, or an effusion of lymph or serum into the subcutaneous cellular texture. She had been in this state for a considerable time, when she was seized with a succession of violent paroxysms of hysteria, which terminated in a state of hysterical affection of the brain, in which she lay in a state approaching to coma, with dilated pupils. She was now attended by the late Dr. Babington and myself. I do not undertake to say whether the disease yielded to the remedies employed, or reached its natural termination; but from one or other of these causes the patient recovered, and from that time she never complained of her knee."

Now the evidence of this having been a local hysterical affection is surely defective. It is so because she was afterwards attacked

by a succession of paroxysms terminating in an hysterical affection of the brain, in which she lay comatose and with dilated pupils. But violent paroxysms, terminating in coma and dilated pupils, themselves require the evidence of coexisting hysterical symptoms, to entitle them to the character of hysteria; unless, indeed, they have yielded to a treatment decidedly antispasmodic; and in this instance the treatment of the cerebral affection is not communicated to us.

I am disposed to think that more valuable practical results are likely to be gained from an hypothesis of paralysis simulating hysteria, than from the reverse hypothesis. Cases of both kinds occur in the valuable "Posthumous Medical Writings of Dr. Parry;" and Dr. Billing has recorded a case in which globus hystericus, with palpitation, ensued in a young man upon a violent strain of the spine, resulting from a fall under a heavy weight.

The tendency to simulate disease, which we are apt to attribute to hysteria, is, in fact, resolvable into our own deficiencies of diagnosis in the existing state of medical science. The same spirit which suggests this view is seen in the tendency to impute a kind of unreality to other phenomena of hysteria. It is an admitted fact that hysteria contains in its list of symptoms a disorder of the faculty of imagination; and thence has ensued the *non sequitur*, that hysterical phenomena are *imaginary*.

But with the fullest admission of the difficulties of diagnosis in hysteria, and which have sometimes been underrated, I cannot agree with a very able writer who has treated this subject—I mean Mr. Goodlad—in his unqualified strictures on the use of the term to explain certain morbid actions. "That which, in its own nature, is *not* permanent," he says, "cannot explain states of action which *are* permanent." Now when the eminent writer whom Mr. Goodlad criticises in these terms, admits the phenomena of hysteria to be fugitive, he is speaking not of the reality of the fact, which we have not yet reached, but of its manifestations to our senses and observation. It is not hysteria which is fugitive, but the hitherto ascertained phenomena of that disease, or of the constitution in which it develops itself, which are so: and we have no right to reject a term expressive of practical distinctions, so far as they go, because they fail to clear up the whole subject. At the same time, it must be confessed that this subject is at present in a state of unwarrantable vagueness; and it is desirable that we should endeavour to arrive at a better understanding as to what we mean when we employ the word hysteria.

Cullen's definition of hysteria, which, as such, has not been improved upon by any nosologist, is as follows:—"Ventricis mur-

* These symptoms terminated in death some months ago.

mure, sensus globi in abdomine se volentis ad ventriculum et fauces ascendentis, ibique stragulantis; sopor, convulsiones, urinae limpidae copa profusa, animus nec sponte, varius et mutabilis." So much for definition. The best description by far is that of Sydenham's "*Dissertatio Epistolaris*." Beside the above symptoms, he gives a graphical account of the *clavus hystericus*; the pains of the back; the swelling of legs distinguished from oedema; the alternate crying and laughing; the palpitation of heart: and he assigns to the diathesis of hysteria the sudden death sometimes occurring after parturition.

The diathesis or constitution of hysteria, indeed, is best described as a tendency to take on and exhibit, under exciting causes, the above symptoms. But if we would render the above-noticed definition and description available towards a sound therapeutical purpose, as an account of the disease, we must remember that those symptoms, many of which, under other circumstances, characterise other maladies, are diagnostic of the disease hysteria only in their collective state. Nor can any expedient enable us to test the quality of individual symptoms (with, perhaps, a very few exceptions) except the ascertained coexistence, or the absence, of such other symptoms as make up with it the hysterical group; unless, indeed, we adopt the method of trying it by treatment upon the one hypothesis or the other.

The following case is an instance of the solution of this question, obtained principally in the first of these ways, though certainly with a very limited induction of such concurrent symptoms.

Mrs. Jones, a lady, æt. 35, of a highly nervous temperament and full person, much exhausted by exertions in the management of a large family, had been confined three weeks, when she was attacked by dyspnœa, pain down the right side of the thorax, and an acute pain on the right side of the face, with pyrexia. The breathing was much quickened; the vesicular murmur complete, but somewhat too strong on the right side; the pulse was sharp, quick, and excited, but not hard. She had nursed her infant. Cupping on that side had been twice performed, when I saw her, with temporary relief of the dyspnœa and pain in the thorax, but a subsequent return of these symptoms. On careful inquiry I found that the symptoms observed periodical accessions. By this circumstance, by the neuralgic character of the facial pain, and, I should add, by the small effect produced by depletion, I was determined to regard the thoracic phenomena as nervous. I selected the liquor arsenicalis as the most appropriate remedy, on this hypothesis,

being less likely to increase heat of skin and action of pulse than cinchona. Five minims of it in camphor mixture were ordered every sixth hour, with requisite attention to the state of the bowels, which had been previously well managed. Upon this plan, within three days, all the above symptoms were entirely relieved.

The necessity that symptoms should be thus tested before they are assigned to the province of hysteria, must remain in force until morbid anatomy shall have explored the organic laws of this disease, or observation enabled us to describe its specific phenomena.

Indeed, until these scientific processes shall have been carried further, we must continue unable even to realise any general model or diagram of the disease. We can possess ourselves of a conception of it for practical purposes only by bearing in mind cases representing it in its most frequent forms.

It may indeed be questioned whether this method of describing or tracing out disease has not been departed from at a too early period in the history of many other diseases. Certainly, it is very often carried unconsciously into effect, by those who imagine themselves to be generalising, while they are actually practising off a single case, and that, perhaps, the last case possessing any common points, that they have witnessed. In fact, the truthfulness which a case possesses recommends it in preference to a generalisation from an analysis of cases. A picture is more agreeable than a diagram. The method however which receives an interest from this latter circumstance, sometimes even where it is not applicable, affords our only justifiable mode of applying our experience, when the limited extent of our acquaintance with the laws of the subject renders an attempt at generalisation hazardous. We are under these circumstances prudent, and not unphilosophical, in taking single cases as representing heads of disease. In this way, then, we should at present endeavour to make ourselves acquainted with hysteria.

Conformably with this view I shall proceed to lay before you four instances of hysteria; by which word, when used alone, I always mean to express the disease, not the diathesis.

I do not consider this division as exhaustive. But I believe these forms to be the most common; and I presume that a suspected symptom might be authenticated, as indicating the presence of the disease, and requiring conformable treatment, or might be disproved as much, according as it is found in combination with the rest of the group.

The first may be termed simple hysteria.

The second is simple hysteria in a more intense form ; in this case, indeed, terminating fatally. The third, hysteria with comatose or lethargic symptoms. The fourth, epileptic hysteria.

First form.—A young lady, of a mixed sanguine and nervous temperament, had enjoyed good health to her 18th year ; her only illness having been a variola, at her 8th year. Playing at ball with some companions, she is seized with giddiness and nausea. Soon after spasmodic movements take place, with no obvious reason ; they return the next and following day ; two months then elapse without further symptoms ; about the end of that time she becomes moody, disposed to solitude, and taciturn ; she now complains of a trembling sensation in the hypogastric region. Presently a lump or ball appears to be rising from that region, and mounting to the larynx, when she has a very disagreeable sense of constriction ; soon afterwards general convulsions, with loud screams, and unmeaning bursts of laughter and tears, and every sort of contortion. A sense of compression also about the hypochondriac region, and a fixed pain at the occiput. She requires to be held with great force to prevent her hurting herself or others. Each paroxysm lasts four or five hours, and suddenly terminates in a copious evacuation of limpid urine.

Simple hysteria running a fatal course.—A young person of general good health is attacked with convulsions in her eighth year, which are not repeated until the period at which the attack to be described commences. She is now aged fifteen years, and has menstruated eight months. The period is then arrested by a fright. The next period is incomplete, and she feels, under its imperfect occurrence, general uneasiness ; a sense of weight in her arms and legs, and anxious apprehensions respecting some duties which she supposes herself to neglect. The next day a sense of strangulation at the larynx and inflation of the abdomen, with convulsive movements of the trunk and limbs. The strangulation prevents her taking the smallest quantity of fluid. A large and limpid flow of urine recurs.

On the third day she is conveyed to hospital. The sense of suffocation increases and she utters loud screams, expressing apprehension that she will soon be unable to breathe ; the abdominal muscles acting with great force. Meanwhile the pulse at the wrist is contracted, hard, frequent, and irregular. The impulse of the heart considerable ; the skin red, and covered with perspiration. In six hours this patient is no more. It is stated by M. Louvet Villermey, from whom I obtain this case, that during these three days nothing whatever of a thera-

peutical kind had been done for this unfortunate person. She was examined.

The stomach was entirely empty, and contracted. The left cavities of the heart empty ; an enormous quantity of black blood in the right ventricle, and yet more in the auricle, much coagulated. The pulmonary artery and the venous system generally filled with black blood. No other abnormal point in the brain than venous congestion.

This case derives an additional interest from the uninterrupted and unmitigated course which its symptoms were unfortunately permitted to take.

Hysteria, with comatose or lethargic symptoms.—A young person, æt. 21, of sound constitution, and regular in regard to catamenia, was crossed by her parents in an attachment which she had formed. Irregularity occurs, spasmodic movements, a sense of suffocation, and the clavus and globus hystericus, with a creeping feel referred to the hypogastric region. Shortly afterwards, a letter from her lover being refused her, she is attacked more violently than before, and she then goes into a state nearly amounting to coma ; she loses all knowledge of persons and things, and power of movement. She has trismus, spasmodic stricture of the pharynx, so that deglutition is impossible. She seems incapable of articulation ; her eyes are fixed ; her eyelids closed. Her pulse meanwhile is soft and regular. This state lasted seven days ; in the course of it she was leeches behind the ears, and blistered, with little obvious effect. At the end of this time she recovered her senses, retaining but little impression of what had passed.

Epileptic hysteria.—The frequent absence of other hysterical phenomena in those who are attacked with this comparatively harmless series of fits, renders the term hysteria somewhat questionable. It rescues this class of cases from imputation of epilepsy, and the prognosis consequent on that supposition.

The first occurrence of a fit of this kind in a young lady of full and healthy figure, and of unskaken general health, whom I attended in 1838, was immediately after eating a hearty supper. But the period had been some time becoming irregular, deficient in quantity, and remote in occurrence. Her general appearance was that of excellent health ; her pulse was soft and quiet ; heart's action sluggish, tongue rather dry. The following facts were communicated to me incidentally : that she had been largely using the nostrum of Mr. Morison, just before the first fit ; that in the early part of her life she had been subject to violent epistaxis ; that the application of some leeches, which bled excessively, had changed this habit, but left her much shaken in strength ; that

she had grown rapidly in early life, then suddenly ceased to grow, and became very large in person; that she was subject to a state of coryza and defluxion from the nose, during which she was always quite free from fits; that they were irregular in occurrence, sometimes happening two or three times a day, sometimes being absent for many weeks, or even months; and that they came on generally with some recognisable moral or physical existing cause.

That uterine obstruction was the agent in this morbid state, I have no doubt. Whatever good I did this young lady, and some was effected, was in proportion to the relief which I afforded her on this hypothesis. Her longest freedom from the fit, while under my treatment, was while she underwent a course of Plummer's pill and extract of henbane, which, even when it did not increase the period, seemed to relieve the circulation, and render the pulse more open.

I have given the above cases, three of them from the valuable work of Mr. L. Villermay, rather as illustrating a principle of division, than as satisfactory specimens of its completion.

All these forms of disease require a method of practice which, as recognised in hysteria, I need not enlarge upon in this place. Confined to these groups of symptoms, this practice is safe, and often curative: extended to certain other symptoms which may present themselves in the hysterically disposed, but explainable on a different hypothesis, or applied to a more limited number of the above symptoms, I have endeavoured to point out that it is fraught with danger and mischief.

It must be admitted that the tendency to confound disease with diathesis or constitution is by no means limited to hysteria. Thus the word indigestion in its general use expresses a habit of constitution. So Dr. Johnson, so Dr. Paris uses it. But indigestion, as treated of by Dr. Wilson Philip, is a certain form of disease frequently recognised indeed in the dyspeptic. It is a subacute phlegmasia of the stomach, or more frequently perhaps of the liver. Meanwhile, those who should practise from his work, unaware of this virtual limitation of its subject, are liable to transfer therapeutics appropriate to the disease in the above sense, to that general habit more frequently characterised by the term indigestion.

If any leave this place with views indistinct and uncertain on the above disquisition relative to hysteria, I beg him to remember, that clearness of distinction must be commensurate with clearness of knowledge; and that hitherto the interesting subject of this evening's lecture has been enveloped in the most intricate obscurity. Meanwhile, let it be also remembered that if we postpone

the work of endeavouring to draw distinctions until our subject has become clear, we neglect the very means by which alone that point is attainable.

EXTRACTS FROM A PAPER IN THE DUBLIN
MEDICAL JOURNAL,

SHewing THE

EFFECTS OF HYDRIODATE OF
ARSENIC AND MERCURY.

Extract from Mr. Carmichael's Cases.
—In one case of lupus, of ten years' standing, in which great deformity had been occasioned by the disease on the features of a young lady on whom all the usual remedies had been tried, the liquor of hydriodate of arsenic and mercury produced most decided benefit, and seemed to put an immediate check to the progress of the malady. In one of my lectures, I stated the case of a man who had lost a great part of the vomer, and in whom much deformity had consequently ensued from an obstinate attack of lupus, who in the course of a few weeks so far recovered as to be discharged from the hospital apparently well. I perceive there has been no relapse of the disease, as he was told to return to the hospital should any suspicious symptoms make their appearance.

In another case in which the nose was affected, and not only the turbinated bones but the vomer had exfoliated, a perfect recovery took place after a three months' perseverance in the remedy.

Dr. Croker's Case.—Bernard Delany (about 8 years old) was affected with psoriasis guttata, particularly of the upper extremities. He got ʒii. of the liquor in an eight-ounce mixture, and took ʒiss. of that mixture night and morning. I tried the use of a lotion (equal parts of the liquor and water) on *one arm* for experiment, and the more rapid improvement of that arm was quite apparent. Soon after, the treatment was discontinued; yet the previous use of the remedy had been so efficacious, that when we last saw him we pronounced him cured.

Dr. Graves's Case.—Mary Cullen, aged 60, had been affected with psoriasis for fifteen years: the disease, at first mild and confined to a few parts of her body, gradually extended over almost

the whole surface of her skin; and when she was admitted into Sir Patrick Dun's Hospital, it presented all the marks of a most inveterate affection. On the 10th of November she commenced the liquor of hydriodate of arsenic and mercury, taking daily three draughts, each containing half a drachm of the liquor. After some days the medicine was discontinued, as it disagreed with both the stomach and head, but it was shortly afterwards resumed in smaller doses; and when the patient's constitution had become accustomed to it, the dose was gradually augmented, and finally she took half a drachm of the liquor four times a day for about two months. The effects of the remedy exceeded my most sanguine expectations, for it caused an almost total disappearance of the cutaneous eruption.

Dr. Irvine's Case.—It would be tedious to relate the entire history of this case: it is sufficient to say, that he took various remedies, Dulcamara and Plummer's pill among the number, without any benefit, unless temporary relief from itching.

From the experience of many cases which I had treated without permanent benefit at the Maison de Santé, with Fowler's solution of arsenic, iodine, and mercury, separately administered, I was inclined to doubt their efficacy; I therefore determined to try the compound of these three. My patient had now been upwards of three months under treatment, and to say the truth was little the better of all the medicine he had taken.

He took a draught containing ʒss , of liquor hydriodatis arsenici et hydrargyri three times a day from the 11th of February to the 28th of April. On the 28th of April the disease was quite cured.

Mr. Cusack's Cases.—I have used the liquor of hydriodate of arsenic and mercury freely in secondary venereal eruptions, both papular and scaly. I found the eruptions yield rapidly to its administration in the dose of one scruple to two, three times each day. In two instances the month became tender, and a slight salivation followed; but in no case have I observed any unpleasant consequences.

Sir Henry Marsh's Case, reported by Dr. Burton at Stevens' Hospital.—James O'Brien, æt. 12, labouring under

a disease having the character of impetigo figurata of strumous origin, covering the face, chest, arms, and thighs, but particularly well marked at the flexures of all the joints. Has been subject for many years to chronic bronchitis, with severe paroxysms of asthma. Curative means were employed, attended with more or less success; but whenever a mitigation of the cutaneous affection occurred, the cough and asthma returned with violence. Means having been employed to alleviate the bronchitic affection, Sir H. Marsh considered this to be a suitable case for an impartial trial of the solution of arsenic, mercury, and iodine (brought before the profession and prepared by Mr. Donovan), with a view to the removal of the skin affection. The dose administered was fifteen minims twice a day, increased gradually to one scruple, and finally given in half drachms. This mode of treatment was cautiously pursued for somewhat less than a month, with a gradual amendment of the cutaneous disease, which entirely disappeared, without aggravation but rather amendment of the bronchial irritation.

Dr. Charles O'Reilly's Case.—In the September Number of the Dublin Journal, you invite such members of the profession as have employed the liquor hydriodatis arsenici et hydrargyri, to acquaint you with the result. In accordance with that request I forward three cases, in two of which the success was complete. The third is considerably improved. Other remedies were employed in all the cases, both by myself and others; such as Plummer's pill, muriate of mercury, iodine, Fowler's solution of arsenic, vegetable infusions and decoctions, such as assarsaparilla, elm bark, dulcamara and articum lappa, with local applications in the form of solutions and unguents, without success. The first was a case of psoriasis diffusa, occupying principally the lower extremities. She was a married woman, and in the fourth month of pregnancy. Aware of the peculiar susceptibility of constitution during that period to salivation, &c. as well as the irritability of stomach that usually prevails during the early months of gestation, I hesitated to employ the liquor of hydriodate of arsenic and mercury at first, but finding the disease becoming more troublesome

and rapidly extending, I commenced with fifteen drops twice a day in a glass of barley water; the dose being gradually increased to thirty. When she arrived at twenty, which was in about ten days, she was compelled to desist from its use, owing to the sickness it occasioned: but not until the disease had completely disappeared, leaving nothing but a slight tinge on the skin. Three drachms only of the solution were administered.

My second case was one of tinea capitis, of two years' standing, in a boy of eight years old. I caused him to commence the solution as a last resource, having employed in vain the means suggested by Bateman, Planche, and Bret, and the parents using the empirical remedies, such as pitch-caps, ointments, &c. so frequently vaunted. The dose I commenced with was six drops three times a day, which I gradually increased to twelve, the largest given. In the space of one month, and before half an ounce had been administered, the disease had totally disappeared. In the case related, I also applied the following ointment to the diseased surfaces: equal parts of iodine and citrine ointments, as an adjunct to the remedy, although conscious from past experience of its inefficacy by itself. The last case was one of syphilitic lepra, rapidly improving under half-drachm doses three times a day. I have also witnessed its good effects in a case of psoriasis labialis. From my experience of its good effects in the above-mentioned cases, I have no hesitation in expressing my opinion, that the profession should feel deeply your debtor for the introduction of so potent a therapeutic agent into the list of remedies.

From the Case-Book of the City of Dublin Hospital.—George McGee, æt. 29, under the care of Professor Williams, was admitted July 14. On both lower extremities and the arms there are several patches of eruption, covered with a scale of silvery whiteness, elevated above the surrounding cuticle; but the scale is not so thick as in common lepra, and more resembles lepra papyracea. They are not painful, but exceedingly itchy. New ones, scarcely the size of the head of a pin, but covered with a scale like the larger ones, are scattered over various parts of the trunk and limbs. They spread

circularly; the scale falling off leaves the cuticle below red and tender, and is succeeded by a larger one which goes through the same process. The head, when shaved, disclosed the crown covered with yellow crusts, thicker and harder than those on the extremities.

Fowler's arsenical solution was prescribed for this man, and after continuing its use for a fortnight, and taking a warm bath twice a week, the eruption is nearly in the same condition as on his admission. The hydriodate of potash was then tried with him, but the lepra resists the hydriodate with the same obstinacy as the arsenic.

The patient was then put on the liquor of hydriodate of arsenic and mercury, five drops three times a day. After *one week's* use the lepra is beginning to yield to this remedy, which has been increased to ten drops thrice a day, and then to fifteen and twenty drops. Under the use of this preparation the lepra yielded slowly but steadily.

Nov. 10. The lepra has disappeared, except three or four half-formed scales on the legs. He now returned to his duty as a sergeant of police.

Case from Sir Henry Marsh, reported by Dr. Buxton.—James Landrican, æt. 12 years, admitted into Dr. Steevens' Hospital, December 16, 1840, under the care of Sir H. Marsh, labouring under a severe form of psoriasis guttata, manifestly of strumous origin: the eruption being most abundant upon the legs from knee to ankle, and upon the arms from elbow to wrist. States that he has been subject to this disease for two years; that it disappears at intervals from some parts of the body, while it shows itself on others; that since its first appearance he has not been entirely free from it; that none of his family labour under any similar affection. His general health is good: bowels rather inclined to be constipated; skin rough and anserine; perspiration very scanty: no internal organic disease can be detected. Sir H. Marsh considered this a suitable case for the exhibition of the liquor hydriodatis arsenici et hydrargyri, prepared by Mr. Donovan.

The patient took fifteen minims three times a day. This was continued during 39 days from date of admission, without producing much apparent effect. The dose was then augmented by fifteen

minims per day, and he was directed to apply a lotion two or three times a day to the eruption, consisting of equal parts of the liquor of hydriodate of arsenic and mercury, and distilled water. He was also placed in the vapour bath every second day. This treatment was continued until the sixty-fourth day from admission, at which time the eruption had gradually but wholly disappeared; the gums showed traces of the mildest insalivation; the general health was much improved; appetite good; skin softer; perspiration more free. He was discharged February 27th; and when last seen, three months from that date, he had experienced no return of the disease.

Dr. Robert J. Hickson's case.—I feel great pleasure in bearing testimony to the happy results which followed the administration of the liquor of hydriodate of arsenic and mercury in the cases which came under my observation. In an indolent ulcer on the temple of ten years' standing, in which the granulations were almost gristly, I tried various stimulants and escharotics, without the least benefit, and at the same time having recourse to constitutional remedies. I then administered Mr. Donovan's liquor, in the manner prescribed by himself, as an internal medicine and as an external lotion, which completely changed the character of the ulcer; it assuming a more healthy appearance, and secreting kind pus. In less than three weeks there was a perfect cure effected. In another ulcer on the instep, in which there was great irritation, I applied the lotion; and in two or three applications the irritability was effectually destroyed, and the ulcer healed by mild dressings. I have also tried its efficacy in a case of sibbens, in which there were high fungous excrescences from the ulcers, as an external application, and at the same time gave it internally. In this case I have also witnessed the same beneficial results, cutting down the excrescences, and completely eradicating the affection from the system.

Dr. White's first case.—Mary Aylmer had been afflicted with that form of disease called psoriasis diffusa, from the period of puberty, her age being now 18, a comely, well-grown girl, but of strongly marked strumous diathesis. The entire of the body, with the exception of the

face and hands, covered with the scaly patches, rough, chappy; the cuticle dry, red, and here and there deeply furrowed; the abdomen and thighs completely covered. She described her sufferings at night as intense, the greater part of which time she spent in scratching the inflamed skin. She had consulted many doctors with occasional temporary (only) benefit. I commenced the treatment by opening the bowels, a full bleeding from the arm, and the warm bath, which last remedy was occasionally used during the course of treatment: she then commenced the use of your solution. She consulted me on the 18th of April, and continued the solution without any other remedial treatment than that above mentioned, and on the last week of June she presented herself perfectly cured, and in the possession of excellent health and spirits.

Dr. White's second case.—A woman, aged 50, five years ago struck her face against a swinging scale in a dark pantry. The pain was not of long duration; but, some weeks after the injury, the part became acutely painful, interfering much with her sleep and general health. A hard rugosity was now felt about half an inch from the ala nasi of the right side, or midway between the angle of the mouth and nose. The progress of the ulceration was slow, the scab occasionally falling off; the edges of the skin being of a violet colour, with a doughy feel. At the time of using your preparation, the disease extended from the spot mentioned to the angle of the eye and nose of the opposite side, and presented the true characters of *lupus* with *hypertrophy*. Her general health good, but wasted with fretting and nocturnal pain: countenance pale, sallow, and cadaverous. I prescribed for her twenty minims of the liquor of hydriodate of arsenic and mercury, to be taken three times a day, with the application of a lotion consisting of equal parts of the liquor and distilled water. She continued taking her medicine until May 17, when five minims were added to each draught. On the 27th, in consequence of sickness and headache, they were discontinued for a week, and resumed and continued until the 20th of June, when they were discontinued, all traces of the disease having disappeared, nor has it returned.

Her general health is much improved, as much from the joy and happiness she experiences at the removal of so unsightly a disease. The lotion was applied frequently with a camel hair brush: the application was followed by a little smarting.

Mr. Jones's case.—I have great pleasure in being able to speak very favourably of the action of the liquor of hydriodate of arsenic and mercury. One case of lupus, in an early stage, came under my notice some time since. Conium, and every means that could be suggested to allay the pain, had been tried by two or three medical men, and no relief being obtained, the poor woman was for trying every thing she heard of. I was asked to see her in consultation with her usual attendant. I found the nose covered with a dark, hard scab, having a tuberculated feeling; indeed, as if there were some split peas under the skin: it was very hot, and the poor creature was quite desponding. It immediately occurred to me that it was a good case to try your remedy, and most gratifying was the result. I ordered twenty minims to be taken night and morning, and a lotion composed of one part of the solution with three parts water. The scab soon came off, the pain subsided, and the nose is now quite well. The scab almost came off in one piece, like the peel off an orange, leaving a healthy granulating surface underneath. I have also under my care a case of tuberculated disease of the skin of the whole face.

Mr. Jones's second case.—On the 4th of April I was requested to see the case in question, and found the whole of the bridge and *alæ nasi* covered with a dense horny crust, of a brown colour, having elevations about the size of a pearl barley, or a little larger, distributed about it; very hot, and painful to the touch. The disease had been of several months' standing, and was slowly but gradually increasing. Various remedies had been tried: cooling applications, stimulants, sedative poultices; but all to no effect: the disease was increasing. She had consulted a physician in the neighbourhood, who ordered the conium poultice. No good, however, resulted; and looking upon the case as one of tubercular disease, I thought it a very good one for trying your solution, and the best results en-

sued. I directed ten minims to be given night and morning, and a lotion composed of one part solution with three of distilled water to be kept constantly applied. In about a fortnight improvement was very evident: the crust afterwards came off quite whole: healthy granulations appeared, and by the middle of June it was quite healed; and the nose is now looking healthy and natural.

Dr. Bigger's cases.—I feel happy in being able to testify to the utility of the liquor hydriod. arsenici et hydrarg. first introduced to the public by you. I have found it useful in cases which had resisted the medicinal powers of the component elements separately. It was in cases of psoriasis that I have principally employed it.

John Gorman, about whom you spoke to me lately, had been afflicted with sycosis in the lower parts of the face and upper part of the neck. He had been treated by various medical gentlemen without success, and had been twice salivated before applying to me. Mercury having failed, I tried arsenic in the form of Fowler's solution, which he took for a long period without the slightest benefit. I then caused him to poultice his face regularly; and I applied a solution of nitrate of silver every second day to the surface whilst soft from the poultice, giving him at the same time half a drachm of your solution three times a day. There was manifest improvement before this plan had been pursued a fortnight; he was able to shave himself, and became more humanized in appearance. At the end of two months I ceased using the nitrate of silver, and your solution was alone employed. In four months from the commencement of treatment he was quite well. I saw this man yesterday, more than a year and a half since he was pronounced well, and he has had no return of the complaint. I should mention, that during the entire treatment he was exposed to the wintry weather, being a car driver: this may in some degree have retarded the operation of the medicine, but it did not cause it to produce any bad effects on the patient.

I feel very grateful to you for your kindness in giving this medicine to many of my poor patients who could not afford to purchase it; and I think the profession are your debtors for the

handsome manner in which you put forward your discovery in the *Dublin Journal of Medical Science*, as such a medicine, if kept secret, would have made the fortune of half a dozen empirics.

Mr. O'Ferrall's cases.—In reply to your note requesting to know the result of my experience in the use of the hydriodate of arsenic and mercury, I am happy to be able to say, that you are rightly informed as to the favourable action of that medicine in many cases in St. Vincent's Hospital. I am bound, however, to add, that in lupus I have not been able to accomplish a cure independent of local means. In certain forms of cutaneous affections the efficacy of the salt is very obvious, although it *has* happened in several instances that the benefit was exactly coincident with the action of its mercurial element on the mouth. Altogether, I consider it a valuable addition to the *Materia Medica*.

Dr. Ferguson's cases.—Since the conversation we had some months since on the subject of your "liquor hydriodat. arsenici et hydrarg." but three cases of any importance, to which I deemed it peculiarly applicable, presented themselves to my notice, the results of which it affords me peculiar pleasure to communicate to you.

Mrs. Dooley, the mother of five children, and nursing one four months old, was admitted into Sir Patrick Dun's Hospital, March 23d, presenting on different parts of her body, particularly the neck and scalp, well marked specimens of *rupia*. No syphilitic taint was suspected. Her constitution seemed much impaired; the disease showed itself on the fauces and palate; the conjunctiva and palpebrae were much inflamed. After preparatory purgation, this woman was ordered a six-ounce mixture with forty drops of the "liquor," to be taken in three doses during the day. This dose was at intervals raised to sixty drops in the day, on the 6th April. On the 19th, this dose was reduced one-third, in consequence of the appearance of some symptoms attributable to the arsenic. The reduced dose, however, was well borne until the 27th of April, on which day she left the hospital in greatly improved, indeed excellent general health, without any remains of the eruption, save tender eyelids. The only other

remedial agents employed in this case were occasional aperients, collyria, and one warm bath.

Miss —, æt. 35, of strumous diathesis, and subject to menorrhagia; for the past two years has laboured under *lepra*, in a rather aggravated form, the eruption being most excessive at the elbows, forearms, thighs, and legs. Had been for the greater part of that time under the care of two most eminent London practitioners, experiencing occasional relief, never entire removal of the eruption. In two months' use of the liquor, beginning with fifteen drops *ter in die*, and never exceeding twenty, the disease has entirely disappeared, and left an apparently healthy condition of the skin. Her general health is decidedly greatly improved.

Woulfe, æt. 50, an old soldier, admitted into Sir P. Dun's Hospital, May 19th, 1842, covered from head to foot with patches of *lepra*, most copious on the legs and back, of some months' standing. After brisk purgation, I ordered him a ʒvj. mixture with liquoris ʒiiss. ʒi. *ter in die*. 23d May.—I raised the dose to ʒij. to the ʒvj. mixture, ʒi. *ter in die*. 27th.—ʒiiss. June 1st.—ʒiij. 7th.—ʒiiss. In this case the medicine has never induced a single unpleasant symptom, but been perfectly tolerated. I have superadded occasional purgatives, with the hot bath about six times, and the beneficial effects already produced by it, I must say, have been quite satisfactory to me; the disease most markedly disappearing. This man's general health is greatly improved since his admission into hospital, and I have little doubt but a very short time will enable me to report his skin *natural*.

Concluding observations.—The foregoing cases have been selected from many in which cures were effected without any peculiarity worthy of observation; and it is by no means to be understood that the experience of the practitioners who have obligingly furnished them has been confined to that number.

In concluding, I may be permitted to make a few general observations on the preceding cases. It may be collected that the elements of which the liquor of hydriodate of arsenic and mercury is composed, do really acquire an increase of efficacy by combination; for we find, that diseases in which

arsenic, mercury, and iodine, had been separately tried without any good effect, were finally cured by the same agents when they were in a state of chemical union. Amongst the changes of properties induced on these substances by chemical affinity, an increase of medical efficacy seems to be one.

Thus, in Professor Williams's case, Fowler's arsenical liquor had been given for a fortnight without the least effect; and hydriodate of potash had no better success. But after one week's use of liquor of hydriodate of arsenic and mercury, in very small doses, the lepra began to yield, and soon after disappeared.

In Dr. Osbrey's case of psoriasis, the patient had been for two years under trial of various remedies without relief. When placed under Dr. Osbrey's care, Fowler's solution, mercury, hydriodate of potash, sarsaparilla, guaiacum, and soda, were used without making the slightest impression. Within ten days after the patient commenced taking the liquor of hydriodate of arsenic and mercury, the eruption began to decline rapidly; and in two months the woman was perfectly well.

In Dr. Charles O'Reilly's cases, Fowler's arsenical solution, iodine, calomel, corrosive sublimate, sarsaparilla, and the whole tribe of alteratives, had been ineffectually employed; yet the liquor of hydriodate of arsenic and mercury succeeded; in one instance, three drachms were sufficient, equal to three-eighths of a grain of arsenious acid; in the other, four drachms.

Dr. Bigger's patient had used mercury largely, as also Fowler's solution, without the slightest benefit; but under the use of the liquor he speedily got well. Dr. Irvine frequently failed with iodine, arsenic, and mercury, separately employed, but with the combination he succeeded.

There is abundant evidence that this medicine succeeds in the worst forms of disease, and sometimes in a very short period, when all the usual modes of cure had failed. Dr. Ferguson's patient had been for nearly two years under treatment, but unsuccessfully; yet in two months, the liquor of hydriodate of arsenic and mercury succeeded, when no more than two and a half grains of arsenious acid had been administered. Dr. Hamilton's patient had been under treatment for eight

years, without any apparent benefit; but when put on the use of the liquor, she recovered in a few months. Dr. White's patient, for years under the use of various remedies for an excruciating psoriasis, was cured by the liquor in seven weeks. On Mr. Jones's case nearly the same observation may be made. Dr. Hickson's patient had laboured under a disease for ten years, which was cured in less than three weeks by the liquor. Dr. Graves's patient suffered from what he denominates superficial lupus for four years, and had been treated in various hospitals with the usual remedies, both internal and external, and with sulphur baths; but all failed. The liquor of hydriodate of arsenic and mercury cured him within seven weeks, when he had taken but two and a half grains of arsenious acid. Dr. Kirby's case of pityriasis had been treated by various practitioners, and resisted every variety of treatment, general and local; after six months' perseverance in the use of the liquor, the disease gave way. The child treated by Sir Henry Marsh for tinea capitis had resisted various remedies during several months, but recovered perfectly under a three months' course of the liquor used internally and externally. Some of Mr. Stokes's patients had also resisted various modes of treatment.

The power of this medicine over lupus is evinced by the cases of Mr. Carmichael, Mr. O'Ferrall, Mr. Jones, and Dr. White. In Mr. O'Ferrall's case, local means were also necessary. Dr. White found the liquor itself adequate as a local application.

That the external application of this medicine, in the form of lotion, is useful, there is sufficient evidence; and this is a property of importance to those whose irritability of stomach and bowels will not permit its internal exhibition. The case of Dr. Croker clearly proves its power as an external agent. The same seems to be evinced by Sir Henry Marsh's second case, in which perseverance in small doses during thirty-nine days did no service, although when the internal use of it was assisted by the external application, the patient speedily began to get well. Mr. Jones's and Dr. Hickson's cases seem also to have received benefit from the local application. I have known several instances in which the external use of

the liquor alone was successful; but they were slight affections.

From the various statements it appears, that slight ptyalism sometimes supervenes on the use of the liquor of hydriodate of arsenic and mercury. This might be expected, inasmuch as each of the three elements of which it is composed is separately capable of producing this result. Arsenic is not so generally known to possess this power; but that it does was proved by Girtanner, of Gottingen, who exhibited arsenious acid largely in syphilis. More lately the fact has been again observed. That iodine possesses the same power is now almost as well known as that mercury does. I have observed, however, that when the liquor of hydriodate of arsenic and mercury produces ptyalism, it does so with less previous soreness of the gums than any other mercurial preparation, and often with none.

Mr. O'Ferrall found the effects of this medicine to be coincident with its mercurial action on the gums. Mr. Cusack observed the mouth to become tender in two instances only. And more generally a cure has been effected without soreness of the gums, or ptyalism, as appears by the silence on this symptom of those practitioners who have furnished the preceding reports.

INTERESTING CASE OF MELANOID TUMOR OF THE EYE.

To the Editor of the Medical Gazette.

SIR,

I BEG to forward you the history of a rather remarkable case which has lately fallen under my observation, and will feel obliged by its insertion in your journal.—I am, sir,

Your obedient servant,

WILLIAM W. COOPER,

Surgeon to the North London Ophthalmic Institution.

308, Regent Street, Nov. 23, 1842.

Mrs. Anne Wright, æt. 62, applied at the North London Ophthalmic Institution, on the 26th of August. She stated that for twelve years she had been subject to attacks of inflammation in her right eye, differing in severity, but always leaving a small red spot just at the outer margin of the

cornea. She had not been in the habit of applying any thing but warm water to the eye during these attacks, and they gradually passed off; the red spot, however, remaining.

Her health has been very indifferent for some years, her appetite impaired, and she is very subject to dyspepsia.

About two months previous to the date of her application, her attention was directed to her right eye by her friends remarking that there was "surely something the matter with it." Upon examination she discovered a small tumor arising from the point formerly occupied by the red spot; but it gave her no uneasiness, and she would not have been aware of its existence had it not been for the observations of others.

Upon examining the eye, I found a tumor of a dark blueish brown colour springing from the cornea, just at its junction with the sclerotica, and encroaching upon it nearly as far as the margin of the pupil. The base was firmly attached to the subjacent parts, and a number of enlarged blood-vessels proceeded from the external canthus, and were lost in its substance.

I carefully examined the interior of the eye, but could not detect the least appearance of disease in the deeper parts. There was nothing unnatural or unhealthy visible about the posterior portion of the globe, and the disease appeared to be quite confined to the anterior and superficial tunics.

Taking into consideration the extent of the attachment of the tumor to the cornea, the doubt as to the depth to which the disease extended in that tunic, and the difficulty of removing it by excision without opening the anterior chamber, and perhaps destroying the organ, I decided upon giving the patient the chance of its destruction by caustic, and applied the nitrate of silver freely. The following day the tumor appeared much smaller, but after a few days it had regained its former dimensions. The nitrate of silver was again applied more freely than before, but with no better success; and the suspicions which I had entertained from the commencement, of the malignant character of the disease, were strengthened.

I lost sight of the patient for a month from this time, but when I saw her again, the disease had made considerable

rable progress, and had assumed a rather formidable aspect. The case was seen at this period by Mr. Fergusson, of King's College Hospital, Mr. Dalrymple, of the Royal Ophthalmic Hospital, Moorfields, and my colleagues, Mr. Coote and Dr. Twining, all of whom agreed with me in considering the nature of the disease melanoid.

The important question then arose as to what would be the best and most judicious course to pursue: extirpation of the globe appeared too harsh a proceeding, as the disease appeared strictly local, and confined to the anterior portion of the eye, and we agreed that an endeavour should be made to remove the tumor from its attachment, and so give the patient the chance of recovery by the less severe operation.

Circumstances prevented the operation from being performed until the 18th of November, when I put it in practice, with the kind assistance of Mr. Fergusson and Mr. Coote.

The lids were separated by wire specula, and the instrument made use of was the convex knife for enlarging the section of the cornea in the operation of extraction.

Upon being grasped by forceps, the tumor gave way, and bled freely; but with care I succeeded in dissecting it cleanly away from its attachments, without injuring the anterior chamber. A doubtful point at the edge of the cornea was touched with nitrate of silver, but there was only one spot which seemed to require it.

The hemorrhage was rather free for a time, but ceased upon the application of cold, and the patient was put to bed, in a darkened room, and ordered to be kept perfectly quiet. Up to the present time not a single unfavourable symptom has appeared. The tumor was carefully examined with two powerful

microscopes by Professor Owen, Dr. Martin Barry, and myself, and the results obtained were as follows.

It appeared to be made up of nucleated cells of a discoid, elliptical form, of various sizes, flattened, and of different degrees of transparency; some

Nucleated cells.

nearly transparent, others full of dark brown colouring matter, like sepia. In some of the cells the nuclei were numerous; in others, not so; and there was considerable variety in size, as well as in form, but the elliptical character was more or less preserved throughout. Many of them resembled the human kidney in shape. In some parts there appeared a congeries of minute cells clustered together; in others, a few larger cells were connected one to the other. The largest was $\frac{1}{2250}$ of an inch in the long diameter.

There were also visible, fibres, which appeared to form the parietes of the cavities in which the cells were developed, and in some parts the mass was principally composed of them, there being considerable irregularity in the disposition of the cells.

The tumor, then, consisted of the above cells developed, and more or less accumulated, in the interspaces of the cellular tissue of the conjunctiva, sclerotic, and anterior layers of the cornea, with a corresponding increase of vascularity and disorganization of the part of the cornea so affected.

The tumor was soft, and of a dark brown colour internally.

I have now, sir, stated all the facts connected with this interesting case that are deserving of notice, and shall be happy to communicate to you the result, whether favourable or otherwise, if I have it in my power to do so.

In conclusion, I must beg leave to return my sincere thanks to those gentlemen whose names I have mentioned, and whose advice and assistance were as valuable as readily afforded.

EPISTAXIS.

To the Editor of the Medical Gazette.

SIR,

HAVING read in your journal of the means Dr. Negrier has adopted in arresting hæmorrhage of the nose, and as every successful case tends to enhance the value of improved treatment of disease, I forward the following, hoping it may find a place in your pages.—I am, sir,

Your obedient servant,
JOHN CHRISTOPHER DAVIE,
Surgeon.

Haddingham, Cambridgeshire,
November 14, 1842.

Richard Cuttriss, æt. 32, a miller, (Oct. 24th), for the last fortnight felt giddiness, and heaviness of head, and this morning was seized with bleeding from the right nostril, which continued for some time. Cold applications to the head, nose, and elevated position. Ordered the following:—

R Magn. Sulph. ʒvi.; Acidi Sulph. Dil. ʒij.; Infus. Ros. C. ʒvi. S. ʒj; 4tā q. h.

25th.—Hæmorrhage again returned from both nostrils to an alarming extent both arms were raised above the head: nares compressed; and in less than two minutes the eruption of blood was completely suppressed. As a precautionary means of avoiding danger, the elevated position of upper extremities, and pressure to the affected parts, were had recourse to for some time after, and I am pleased to say, with the happiest results, the effusion not having returned. The patient stated he had ten different attacks of bleeding; supposed he had lost in the whole a gallon of blood: upon the last occasion he lost more than a quart, besides what was swallowed.

For some days after his head was not free from uneasiness, and bowels constipated. Relieved by resinous aperients, and he has resumed his occupation.

SURGICAL CASES.

To the Editor of the Medical Gazette.

SIR,

SHOULD the following cases meet your approbation, you will oblige me by

inserting them in your valuable periodical.—I am, sir,

Your obedient servant,

JAMES D. BROWN,
M.R.C.S.

Haverfordwest,
Nov. 24, 1842.

Congenital vomiting.—A boy, 12 years of age, was brought to me from a distance of 18 miles, by his father, who stated that his child vomited every thing which he took either in food or drink, although the whole did not come back. The boy had been under medical treatment from infancy, but received no benefit whatever.

He seemed short, but stout, for his age; had a healthy appearance; his bowels were costive; thirst moderate; tongue clean and healthy; appetite good; and he vomited easily, without feeling nausea.

I carefully examined him, but could detect nothing wrong in his system to account for the vomiting; neither in the stomach, spine, nor head. I became incredulous about the case, when the father desired him to eat part of an apple which he gave him. He had eaten three mouthfuls, when he suddenly stopped, and back it came, mixed with a little saliva, &c.

I thought the affection essentially nervous, depending on excessive sensibility of the pneumogastric, &c., and concluded that, by allaying that sensibility, I should cure the boy.

I ordered him to live on milk and curd; to eat little at a time, but to eat often; and gave him ten drops of tincture of opium, and two of prussic acid, P. L., three times a day, in thirty drops of water. After taking the second dose the vomiting did not return. He took the medicine for two months, and is quite well, and much improved in appearance, and can eat any thing. He has now been well for four months.

Nervous affection.—A girl complained of a peculiar pain in the palmar surface of the index finger of the right hand; it was very sensible to the touch, and prevented her from sewing, &c. &c. as pressure gave her a stinging pain: it had been so for six years, and occurred directly after pricking it with a thorn: she thought that a part was still in the finger.

On the supposition that a nerve had been pricked, and partially divided, I made three or four deep incisions, so as to divide the nerves; and dropped into

them a strong solution of nitrate of silver: the parts quickly healed, the pain ceased and never returned, and she is quite well.

Lupus.—A young man came to me with lupus of some months' standing: part of the ala nasi was destroyed: the disease was progressing rapidly: no application had been made hitherto.

I gave him 5 grains of iodide of potassium, and $\frac{1}{2}$ of a grain of iodine, three times a day. I touched the part with nitrate of silver every three days. He got rapidly better, and was well in three weeks.

Scrofulous ulceration of the upper lip.—A girl had suffered seven years from an enormous enlargement of the upper lip, with superficial ulceration: it rendered her so disgusting that people refused to work in the same shop with her (she was a factory girl): various means had been adopted, but in vain.

I applied the chloride of zinc paste three times, allowing a week to elapse between each application: in three weeks it was entirely healed, leaving no thickening, and now seems quite natural. The paste consists of equal parts of flour and chloride of zinc.

Uterine hæmorrhage.—I attended a woman, æt. 34, in her fourth confinement: she was a person of lax fibre. The labour was natural, and terminated in six hours; but a violent fit of shivering seized her before the expulsion of the child. I was prepared for the event; and, as I expected, flooding came on to a fearful extent. The placenta was loose, and came away with the first gush. The uterus again dilated, but I passed my fingers into its cavity, in order to excite it to contract, &c. and at the same time made pressure externally, but hæmorrhage still continued in spite of every effort—pressure, cold applications, &c. &c. She had fainted, and recovered, and was suffering from the effects of the loss of blood.

I decided on trying the effects of pressure on the abdominal aorta. I had no difficulty in finding it. I made firm pressure on it, which gave the patient some pain. The hæmorrhage ceased directly, and did not recur: I had it in command: to feel satisfied of that, I gently relaxed my grasp once or twice, when bleeding again commenced.

I still kept up pressure on the uterus,

and administered secale cornutum in brandy and hot water. The woman rallied, the uterus contracted firmly and permanently, and I let loose the vessel, after pressing it for nearly two hours; and all went on as well as possible.

A similar case occurred to me, in about two months after. I adopted the same means, and with the same pleasing and important results.

I found no difficulty in finding the vessel, but I imagine there would be in a stout woman (unless the recti muscles were separated), but even then, relaxing the abdominal muscles would, I think, be sufficient to allow the hand to reach the aorta. I must confess that I thought it a difficult undertaking before I tried.

Some authors recommend it to be pressed from the interior of the uterus, which may be done when it cannot be got at *otherwise*: the one plan is not free from danger, the other is completely exempt.

I am surprised that so important a measure is not more general—a measure the principle of which is acknowledged in the most trifling surgical operations, the effects of which are certain and immediate, and the result the saving of life.

Squinting.—I have operated on 31 cases of internal strabismus with good success. In all but one I was aware at the time that it was a failure, yet I could not remedy it. The muscle was divided, the sclerotica cleared from all bands of cellular tissue; yet the eye remained as at first. I did not divide part of the inferior rectus, as Liston advises and practises, not knowing at the time that it had succeeded in such cases as mine; but should a similar case occur I will try it.

In one case the eye started forwards and outwards, and became more prominent than natural, but it was a catarrhous eye; yet withal, the appearance was much improved.

The sight is invariably improved in all cases where it was faulty before.

Frequently both eyes are implicated. I do not cut both the same day, fearing that the patient may not keep his eyes straight long enough to prevent the muscle from adhering too near to its former place. I tie up the uncut eye for four days, so as to prevent its influencing the other until all chance of the

muscle adhering too close to its former place is over: then I cut the other muscle, and uncover both eyes. It is positively necessary to operate on both eyes, when they are both implicated, although one is generally in a less degree than the other.

Certainty of the muscle being cut, and the eye free, is known by the total inability to look inwards, towards the nose, to that extent which the other eye is capable of. No surgeon should rest satisfied until he obtains that point, but should carefully clear the sclerotic coat from strong bands of cellular tissue which frequently are met with in such cases: if that fails, the incision in the conjunctiva should be enlarged freely, which I think, in some cases, tends to assist the cure; and in fact, I have seen a case in which a *free* incision answered, and where a *small* one failed, after the muscle was divided. In short, it is reasonable to suppose that the conjunctiva is, in some cases, quite sufficient to retain the eye; the slightest resistance acting constantly must overcome a greater acting irregularly. Duffin mentions cases of *relapse* cured by reaction of the conjunctiva.

If all fails, I believe cutting a part of the inferior rectus will answer: Liston has found it succeed. It is very difficult to recognise the muscle at times; sometimes it is very thin, and liable to be confounded with the cellular tissue; at other times very large, and easily recognised. I have seen it closely covered in by strong cellular tissue, so as to prevent the hook from seizing the muscle until it was properly cleared. In all cases a bold and free incision is best, one that will expose the muscle at once, free from its covering. The operation is sooner over, and gives less trouble and pain.

External strabismus.—A girl had external strabismus in consequence of paralysis of the third nerve; she had ptosis too, which was remedied by cutting a piece out of the upper lid in the usual way. I divided the external rectus as an experiment; the case was not benefited.

I have stated all the difficulties I met with, hoping they may be of use to beginners.

ON THE PERIOD OF PUBERTY IN NEGRO WOMEN.

To the Editor of the Medical Gazette.

SIR,

I READ, with much interest, Mr. Robertson's observations on the subject heading this short communication.

I believe this gentleman's views, relative to the supposed earlier period of puberty in the natives of tropical climates, for the most part correct. So far as my observation goes, however, but without having made any specific inquiry, I am of opinion that the period of puberty is of earlier occurrence in inter-tropical regions than elsewhere.

It is quite within my recollection to have observed very young negro girls on the coast of Africa, with the developed mammae, and other attributes of puberty, living in the capacity of wives, or mistresses, to the natives and others.

While I consider negroes in point of intelligence fully on a par with Europeans, I have always found it extremely difficult to ascertain their ages: when a question is put to them to this effect, they are quite unable to give any satisfactory reply. Judging from appearances, however, I should say that I have seen young persons, as wives and mothers, at the early age of fourteen. It is obvious, therefore, that this question can only be satisfactorily settled by those missionaries, medical practitioners and others, who have an opportunity of seeing the natives of inter-tropical regions from infancy upwards.

In other respects, women in these countries frequently menstruate, and consequently become nubile, at a much earlier period than is commonly supposed. I knew a young person who menstruated regularly at and after the age of eleven. I have also known menstruation to occur from the ages of twelve, thirteen, fourteen, and so on severally. Prostitutes, apparently of not more than twelve or thirteen, unhappily frequent the streets of most of our large towns. I saw a young woman brought in for delivery into the Dublin Lying in Hospital, in the year 1824, whose avowed, indeed apparent age, was only thirteen!

I remain sir,
Your obedient servant,
HENRY M'CORMAC, M.D.

Belfast, Nov. 20, 1842.

CASE OF HAY FEVER.

To the Editor of the Medical Gazette.

SIR,

THE following case may, perhaps, interest your readers, and is at your disposal.—I am, sir,

Your obedient servant,

R. R. CHEYNE.

43, Berners Street, Nov. 21, 1842.

Mrs. —, æt. 28 years, living in my neighbourhood, of a good constitution, and the mother of four children (the youngest being six months old, and at the breast), requested my advice on the 22d of September last. She had been suddenly attacked, the day before, with pain over the brow, soreness of the eyes, copious discharge of tears, sneezing, great dyspnœa and cough, with some pain in the chest, extending to the back, between the scapulæ. These symptoms continued severely whilst she remained at home, but left her entirely in the afternoon in the course of a drive towards Islington, where, having on her way ascertained my absence from town, she was about to seek advice. She returned home again in the evening, when she almost immediately suffered another attack of the same nature, which continued, more or less, through the night. I saw her the next morning, and observed symptoms like those above described; in addition, the stethoscope gave no indication of disease within the chest, more than deficient respiration consequent upon spasm. I advised antispasmodics and expectorants, which did no good, and then cupping between the shoulders, and the application of blisters, with very slight effect upon the complaint. In fact, the intervals between the paroxysms became daily less distinct; so that on the 28th, when Dr. Watson met me in consultation, the dyspnœa, &c., were nearly constant in a greater or less degree, and as an effect, not a cause, there existed excess of secretion from the bronchial mucous membrane.

Having found all the customary remedies totally inefficacious, I now looked around me for the reason of failure in some constitutional peculiarity on the part of my patient. I had observed a strong odour of hay upon entering the house, and, on inquiry, was told by the husband (a

stable-keeper) that his lofts were filled with hay, lately brought in, which, as he said, had an unusually powerful smell. I learnt, also, that my patient was always worse when the house was closed at night, and better in the morning, when there was a free current of air passing through the open windows. After carefully thinking over these facts, I was led to view the symptoms as depending upon a peculiar susceptibility to the effects of the flowers of grass, and to believe the case to be what has been named hay-fever, or asthma. In this opinion Dr. Watson concurred, and we accordingly advised our patient to take lodgings, without delay, away from the probable source of irritation. This advice, however, was not acted upon until two days afterwards, and, meanwhile, the disease continued to increase in severity, having resisted the influence of Hoffman's anodyne, which Dr. Watson had prescribed. At length, our patient removed into apartments situated about a hundred yards from the spot, and the immediate result was most striking and satisfactory. All the distressing symptoms at once subsided, and the first perfectly tranquil night was passed since the commencement of the attack. So complete and permanent was the relief experienced, that no further aid from medicine was required than the exhibition of a few doses of quinine, for the purpose of restoring the strength, and restraining within its natural limits the bronchial secretion. Our patient then went into the country for a fortnight, where she entirely regained her health, having previously lost every vestige of her complaint. As soon as she ventured home again, and during a few weeks afterwards, she suffered from slight cough, and some occasional dyspnœa; at the present time, however, she may be said to be free from either symptom. It is worthy of remark, that before her return to town a new stock of hay had been substituted for the former, which fact may, probably, explain the comparative immunity she now enjoys. However, it is more likely that the resistance—opposed by the nervous system when again within the sphere of the irritating agent—proceeds from the present increased vigour of our patient's constitution, which, previous to the first attack, had been a good deal impaired by suckling a strong

infant throughout an unusually hot summer.

The existence of the almost incredible idiosyncrasies of certain individuals is confirmed by daily observation. Thus, it is well known that some persons are affected with dyspnœa from the odour of the smallest particle of ipecacuanha. In others, again, the aroma of various flowers excites fainting, and I am acquainted with a lady in whom the same effect is produced by the odour of the pine-apple, or of the least quantity of whiskey. A number of other instances of a similar kind might easily be adduced; in every case the phenomena depending upon irritation of the sensitive nerves of the mucous membrane, and the reflected influence from the brain, &c. In the case above detailed, in which the symptoms seem clearly to have arisen from exposure to emanations from the flowers of grass, the cause of irritation was applied to the whole extent of mucous membrane from the nose along the pharynx and larynx to the lungs, being conveyed by the sensitive nerves of these parts to the nervous centres, and reflected back to the respiratory muscles. Certainly, the case very beautifully illustrates the series of actions that govern the sympathetic respiratory movements.

ON THE HEALTH OF SOLDIERS AT SEA.

By FREDERIC ROBERTS,
Assistant Surgeon, 59th Regiment.

(For the *London Medical Gazette*.)

On the 2d of January, 1841, the right wing of the regiment, consisting of 372 men, women, and children, to the West Indies, and some invalids for Malta, embarked on board H. M. Ship "Sapphire," a twenty-eight gun frigate, with her guns out; affording excellent accommodation; the height of her main deck being six feet seven inches, and of lower six feet; carrying plenty of water in iron tanks, provided with wind-sails, and funnels at the sides communicating with the lower deck, and furthermore a dry vessel, and good sailer.

Geographical situation.—The voyage commenced in lat. 39° N. and Long. 20° E., varying little in latitude as far as

Gibraltar, when our course lay in nearly a south-westerly direction, till we reached Barbadoes in lat. 13° N. and long. 59° W. and from hence N. N. W. to Antigua, in lat. 17½° N. and long. 63° W. On reaching Barbadoes we had consequently made 22° to the southward, and 83° to the westward. Though three months on board ship, the monotony of the voyage, and the quality of the food, were agreeably changed by lying for several days in harbour at Malta, Gibraltar, Barbadoes, and Antigua.

Meteorological phenomena.—On the day of sailing from Corfu, the thermometer stood at 60°, and at the completion of the voyage, as a natural result of our position on the globe and progress of season, 83°; making a difference of 23°; but the extreme range was 35°—the mercury having fallen as low as 48°. The extreme range in the day was never more than 10°. The change in the temperature may, then, be said to have been gradual till reaching the tropic of Cancer, when it increased with greater rapidity (in the ratio of exactly one degree daily). The prevailing winds, while sailing in the Mediterranean, from 2d January to 28th of February, were N. W., W., and S. W. with frequent strong gales, occasional rain, and a moist atmosphere. In the Atlantic the wind blew with uniform force from the east, and its collateral points.

The return of sick during the voyage (exclusive of invalids landed at Malta) is submitted in Table No. 1, and the nature of the diseases is shown in No. 2.

TABLE I.

Corps, 59th Foot.	Strength.	Total number of sick admitted.	Number of deaths.	Sent into hospital at Gibraltar.	Average daily sick	Remaining.
Officers and Men.	307	67		1	84 $\frac{9}{10}$	
Women.	23	10			14 $\frac{4}{10}$	
Children.	42	24			32 $\frac{3}{10}$	

Corps, 59th Foot.	Fever.		Diseases of the chest.		Diseases of the liver.		Diseases of the stomach and bowels.		Rheumatic affections.		Diseases of the skin.		Wounds and injuries.		Phlegmon and abscess.		Diseases of the eyes.		Venereal diseases.		Ulcers.		Other diseases.		Total.

Total . . .	14		17		1		18		2		11		13		8		5		3		4		5		101	

TABLE II.

Review of the prevailing Diseases.—The fevers among all classes were epidemic, and require no notice. The diseases of the chest were slight catarrhal affections, and one case of consumption in a recruit, who was left at Gibraltar. These affections were observed most conspicuously to occur during the gales of wind, and it was then the children were attacked almost entirely.

Diseases of the stomach and bowels.—These were principally slight cases of diarrhoea, the greater part of which happened on the voyage from Malta to Gibraltar, the longest period at sea and deprivation of fresh meat, and during which the weather was coldest and most wet. But few cases of constipation occurred.

Diseases of the skin.—These were cases of "prickly heat" occurring on reaching the warmer latitudes, chiefly in children. This species of prurigo yielded immediately to sulphur.

Wounds and injuries were cases of more or less severe bruises and cuts received in working the ship, and in falling down the hatchways during the gales. One man received a concussion of the brain and injury to the back by the falling of a quarter of beef from the fore-topmast head upon him in a gale of wind. I introduce his case for the purpose of shewing that he was ultimately attacked with scurvy. He was of a phlegmatic temperament, and prone to indolence at all times, and made but slow progress towards the recovery of the injury. Having been under treatment for five-and-twenty days, still in a weak and listless state, an inelastic swelling of the legs and feet, with livid blotches, swelling of the gums, slight hæmorrhage, loose teeth, fœtid breath, and lassitude, became apparent; and in nineteen days after, his health was completely recovered by the use of quinine, lime juice, preserved meat, and wine. Whilst slowly recovering from the injury, it is instructive to observe that this man was attacked with scorbutic disease; certainly when he had been much reduced, and when lying in an inactive state during the coldest and most moist weather we met with; but he had been several days in Malta harbour, and had never tasted salt meat since he had been on board, and had been fed on

wholesome farinaceous diet whilst sick. It would appear, therefore, that the exciting cause of scurvy, under circumstances of debility, with exposure to the predisposing influence of an atmosphere charged with moisture, as it must be generally at sea, may be very slight.

Phlegmon and abscess.—Under this head are placed some cases of boils which occurred during different periods of the voyage, and which were observed to come early to maturity.

The cases of diseases of the eyes were infection of the conjunctiva without purulent discharge, which occurred when the men were exposed during the gales to continued streams of strong wind, which irritated the membrane by its force and constancy.

Ulcers and other diseases were slight and few. Sea-sickness effected little inconvenience, except at first, and that among the men and women chiefly: the children being remarkably free from it.

A remarkable exemption from disease at sea will be perceived in the above tables, which show, in round numbers, the average ratio of admissions for *three months* to be 22 per cent.; whilst Major Tulloch's Reports show the same *annually* to be among the cavalry in the United Kingdom nearer cent. per cent., and in the Prussian army 111 per cent. The average duration of each attack, for three months at sea, among 307 men, is 12 days; whereas, among 1000 dragoons at home, it is 16 days: showing further a greater degree of severity in diseases on shore. The medical records of the corps likewise show the average daily sick for eight months at Corfu, where its average strength was 629, and where it was at first sickly, to have been 54. The previous year at Malta, out of an average strength of 505, it was 26; and on board ship, the strength being 307, it was nearly 9.

In comparing the relative extent of sickness among the troops on shore and at sea, we eagerly avail ourselves of the opportunity of shewing (as far as can be determined from a small number and a short period) the salubrity of a sea voyage, and its tendency to re-establish the health of the men, on removal, as in the present instance, from a comparatively healthy to an unhealthy station, and enable them to withstand the severity of climate—an argument, were there any wanting, in favour of the system of

relieving regiments *often* in foreign stations.

Much has been said and written latterly respecting the causes of disease in the army: it is not our intention, however, to speculate upon so intricate a subject: but a circumstance of so marked an aspect as we have shown above has naturally led us to notice those circumstances which appear to modify the influence of the physical agents on the body. Knowing what wonderful difference in corporeal structure is produced by the physical agents, even in a state of health (familarly exemplified in the physical conditions attained by prize-fighters and jockeys by training, and in many defective corporeal states, in which, however, it must be understood, the functions of life are performed with comfort and a sense of well-being), it is but reasonable to consider that a large proportion of disease is the result of some irregularity in the application, or of an altered mode of operation, of these agents. The history of disease shows that “although seemingly contradictory facts and complex circumstances present themselves amongst the alleged causes of disease, still the removal of these causes, by attention to food, drink, draining marshes, and airing dwellings, &c. &c. have often removed these evils;” although even “*these causes have been shown to be at variance with numerical results*”*.

In addition to what has been premised at the commencement of this report, we shall finish the description of the physical position of the troops at sea, by remarking that the soldier's diet on board ship is good, and properly regulated; and, from the nature of his situation, relatively more abundant, and is always varied by the issue of fresh meat in harbour, and for some days after. He is not subject to the influence of intemperance, but receives his quantity of grog daily, with the addition, after a certain period, of lime-juice—a means of obviating, under general circumstances, a disposition to scurvy, and an intention which is only marred by converting its stoppage into a means of punishment. His habitation is crowded; but the means for renewing the fresh, and for the escape

* See Statistical Reports of Sickness in the British Army. By Major Tulloch.

of the heated air, so well obtained through the hatchways, wind-sails, and funnels, appears to obviate all injurious effects, especially when aided by frequent cleaning and sprinkling of chloride of lime on the decks. The plan of dividing the men into three watches, one of which is kept constantly on deck, and keeping the women and children above when the weather permits, pretty fairly compensates for the deficiency of fresh air below at night. Cleanliness is insured by frequent inspections after washing the greater part of the body. The working of the ships, which requires more mental energy in the exercise of a mechanical talent than the soldier is called upon to exert on shore, music and dancing, reading, and the novelty of situation, divert the mind, and contribute to the support of his health. His rest, too, which, on the average in the last two stations was disturbed every three nights and a half, and exemption from inclemency and vicissitude of weather, in conjunction with the above moral and physical conditions, operated so much, in this instance, on the health of the men, that, on landing in the West Indies, they presented buoyant and vigorous frames; and for many days previous not a man had been sick.

The circumscribed situation of a soldier on board ship would appear to render the causes of his complaints more palpable, and, in a properly regulated vessel, to bring them more under control—a circumstance that, besides attracting attention to the correction of the influence, and encouraging endeavours to elucidate the mode of operation of the physical agents, would suggest the nicer search from analogy of the causes of diseases on shore.

Antigua, April 25, 1842.

ON THE
SPLEEN AS A CONTRACTILE ORGAN
PROPELLING THE BLOOD
THROUGH THE VEINS.

To the Editor of the Medical Gazette.

SIR,

A FEW remarks on this important question, as lately advanced in the form of what I consider to be little more than pure hypothesis, may not, I think, be uninteresting to the profession. Mr. Jack-

son has, as is well known, laid before the public some peculiar views on the use of the spleen, placenta, &c.; tending to the conclusion that the placenta and spleen are vitally contractile organs, capable of acting intermittently, and as real adjuvants to the circulation of the blood.

After a careful perusal of the original work, I am led to the conclusion that there is no ground whatever for believing the spleen to be a vitally contractile organ. The arguments adduced by the author in favour of such an opinion are the following: viz. 1st. The experiments made by Magendie; the injection of fluids into the circulating mass, when the spleen becomes enlarged, and the diminution in size of the same organ in animals bled to death, or fainting. M. Magendie observed the same effect in the liver, under similar circumstances. But these experiments cannot, I think, be considered as the slightest proof of any thing more than that the spleen is an elastic organ, ordinarily existing distended to a certain extent, but capable of further distension by influx of more blood. Our author finds a regular relative proportion between the spleen and the liver in man and other of the higher animals; he describes it in man as 6 to 1; and in quadrupeds as 12 or 16 to 1: whereas, MM. Bichat and Cruveilhier say that “the spleen varies so much in size, that it is almost impossible to say what are its normal proportions.” The next argument is founded upon the fact that strychnia, morphia, ergot, &c. produce contraction of the spleen. But here it must be recollected that in the cases alluded to, death has taken place in one of two ways—either the animal has died violently convulsed, or (as in Mr. Wright’s cases of ergot), they have lingered, become extremely weak and emaciated, so as to die of exhaustion. This latter condition, in consequence of the great diminution in the volume of circulating fluid, reduces the system to the same state as in Magendie’s second experiment; and in those animals which die convulsed, we cannot wonder at the spleen being diminished in volume, if we regard the enormous compression all the abdominal viscera must be subjected to by the powerful muscular contractions.

But let us suppose the spleen to be a

decidedly muscular organ, similar even to the heart, and contracting like it intermittently. Would this, then, answer the purpose assigned to it? Certainly not. The vena porta does not only receive blood from the spleen, but the larger part* of its volume is contributed by the superior mesenteric vein. The splenic vein would not be able to suck up the blood from this vessel. So that I think we have two most powerful reasons for not assigning any such function to this organ: 1st, because we have not the slightest evidence of its contractile power (*i. e.* more than that of elastic tissue in other parts, mere elasticity), and 2d, because even if muscular, it could not answer the desired end. Had the mesenteric vein been very small, its blood might have been taken up as the contents of the thoracic duct into the junction of the jugular and subclavian veins. The ordinary experiments, (as contrived by Bernouilli) proving the friction of fluid particles on each other, illustrate the necessity of rapidity of current, and disparity of size of the tubes.

Did the spleen perform so important an office, its removal could not take place without marked disturbance of the biliary and digestive apparatus. On this point Mr. J. says (p. 85), "When we reflect that other organs, as the uterus and kidney, have been lost; that in *hernia cerebri* a portion of the brain has been sliced off; that one or more, or even all the extremities, have been amputated, and that notwithstanding such mutilations patients have recovered, it does not appear so extraordinary that the loss of the spleen is not necessarily a fatal occurrence." Had the spleen been of the importance assigned to it, it would have been a very extraordinary circumstance for the digestion to be perfected, bile well formed, and the body to thrive, whilst one of the vital organs, (as it then would be) were absent. But I consider this to be one of those statements continually made by authors who are attempting to establish a theory, and that it shows how blind they are. The fact is, the parts mentioned by the author are not any more vital than the spleen as it naturally exists is. Had the spleen performed the office assigned, its absence ought to cause great disturbance—

arrest of nutrition, and finally death. Is it so with a leg or an arm? or a uterus? or even a kidney? The parts here mentioned, we should much wonder if their removal did occasion any permanent mischief, (the operation whether artificial or accidental) omitted. We know if one kidney be lost the other performs compensating function; and if a slice of brain be lost, according to the opinion of the phrenologists we should have some cerebral function lost. But take away both kidneys, or the whole brain, the animal will die. Supposing the spleen to answer the proposed end, what part can perform its functions when extirpated? None. In fact, the spleen really cannot be for any such purpose. The author himself says, "in dogs, after extirpation of the spleen, *the undiluted blood filters through the liver, and flows into the general system by the hepatic veins as fast as it is admitted into the trunk of the portal system.*" If the spleen, then, be the propeller, how is the blood propelled during its absence? Our author argues, that because the branches of the portal veins are surrounded by cellular tissue, and collapse when examined after death, the flow of blood is not constant but intermittent. But such an induction is not necessary: it is much more probably so arranged for the sake of permitting distension; at least we find other such arrangements in other parts of the frame.

We find it mentioned that dogs, after having had the kidneys extirpated, micturate oftener than other dogs. This, it ought to have been stated, has been denied by two excellent authorities, viz., Tiedemann and Gmelin. The author next explains why this takes place, and to finish, produces an example of just the reverse, viz., Mr. Ferguson's case, where a man lost a great part of his spleen by gangrene, and constantly complained of difficulty in making water. Considering, therefore,

1st, That there is no evidence of the spleen possessing any more contractile power than is quite consistent with elasticity;

2d, That if it were even muscular it could not answer the proposed end;

3d, That it may be removed from the body without material alteration of the biliary and digestive functions;

4th, That the circulation in the liver can be explained in a more rational

* Cruveilhier: Anatomie.

manner (although if it could not, it would be better to acknowledge ignorance, and make more experimental inquiries than to rest satisfied, feeling assured that we are wrong).

I think the principle in hydrostatics, of fluids*, in bent tubes, finding their own level, will adequately explain the mode in which the blood arrives at the portæ from the spleen and the superior mesenteric vein. This also explains the passage of blood up the inferior cavæ. The use of the hepatic veins terminating in such large and always open branches, is readily understood by looking at the forces causing the right ventricle to be filled.

I believe, with Dr. Billing, that the principle above mentioned is a grand cause of ascent of blood in the inferior cava; this, also, as I have said, explains the means by which the blood ascends from the spleen and superior mesenteric vein; also it enables (what we find to be true) the circulation through the liver to be carried on, notwithstanding the removal of Mr. Jackson's hepatic heart. This also explains the use of valves in veins in which they are found, and gives us a reason for their absence under the opposite circumstances: for instance, wherever the veins are exposed to the influence of muscular contraction, there we have valves; but in the veins of the cavities we have none. Another power by which the blood is impelled into the right auricle is the expansion of its walls, be it active or passive. I think myself it is really passive. When, then, the auricle contracts and propels its blood into the right ventricle, the auriculo-ventricular valves prevent its return; the auricle then expands, and what must be the consequence? the blood flows in from the cavæ; to assist this, I consider the large hepatic veins remain open and filled with blood, as stated by Mr. Jackson. The right ventricle, also, by its dilatation, would tend powerfully to draw the blood from the right auricle, were the walls of the latter not muscular. I cannot conceive that this influx is at all connected with either inspiration or expiration. If so, as the pulse is ordinarily in the ratio of three to one to the breathing, we should only have

the auricle filled once during every three contractions of the heart.

I may take this opportunity of stating my opinion in regard to one statement made by Dr. Billing, viz., "in inspiration there is no suction, for the glottis is sufficient to admit a free current of air." "Such an opinion is inconsistent with the laws of physics." If there be no suction, why does the air rush into the chest? That suction, then, really exists, appears to me quite obvious; so much so, that I am surprised to find so talented and accurate an observer make such a statement. The explanation of the use of the spleen given by Mr. Dobson appears to me, as well as to some of our first physiologists, as a very rational one; he says it acts as a safety-valve, so as to prevent any ill effects at times when the circulating system would be loaded by its distension, and contraction when that dilatation was over. This fully explains why its size so varies; why the vena portæ is surrounded by cellular tissue and distensible; why it has such thin coats, quite contrary to vessels which are exposed to any vitally contractile force; and why patients who have lost the spleen suffer from hæmorrhage occasionally. I now take leave of this subject, hoping that I have thrown a little light upon the matter; and I shall take another opportunity of attempting to show that the use of the placenta and its "vital contraction" are considerably more questionable than our author supposes.

I am, sir,

Your obedient servant,

A CONTRIBUTOR.

London, Nov. 25, 1842.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Essays on Determination of Blood to the Head. By ROBERT HULL, M.D. &c. London and Norwich, 1842. Small 8vo. pp. xlv. and 154.

OUR ingenious and learned correspondent, Dr. Hull, has written these essays in order to warn students and practitioners against the abuse of blood-letting; and he has conveyed his in-

* Described by Dr. Billing, *Principles of Medicine*.

structions in a style where good sense, good humour, quaintness, and classical quotation, are so agreeably intermingled, that one could hardly wish any of the ingredients to be absent. Thus, to take the case of *Laridus*, who had received a gash in the abdomen from an assassin.

"It was a horrible chasm to look into; with its perpendicular walls of fat; but there existed no evidence that the abdominal cavity was laid open. But the surgeon, a most accomplished practitioner, bled him again and again, over fearful lest peritonitic symptoms *should* arise. He died. The cavity of the abdomen was entire. But it was found that the deep chasm was as the assassin had made it. No lymph had been thrown out to consolidate the surfaces, which, instead, were sloughy and universally discoloured. He died, the victim of the friendly, not the hostile weapon.

ἔκων γὰρ ὅλεσάς νιν. ἀνθρώποισι δὲ,
θεῶν διδόντων, ἕκδς ἐξαμαρτάνειν.

Touching the use of the lancet in capital disorders, I am not pretending to depreciate it, when needful, nor to direct it in the numberless varieties of disease. I only wish to impress upon the student; and all are students, who are even practising physic; that in medical, as well as judicial, conditions, the doubt should tell in favour of the pannel. So sacred is blood, do not spill it upon conjecture."—p. xxii. iii.

"*Cephalea Siphylitica*.—Here the diagnosis is the important affair. Some think the intermittent, nocturnal character of the ache to be decisive.

Intermissa, Venus, diu
Rursus bella movent."—p. 59.

Clinical Midwifery: with the Histories of four hundred cases of difficult Labour. By ROBERT LEE, M.D. F.R.S. &c. London, 1842. Small 8vo pp. 224.

OUR readers are well acquainted with the labours and the merits of Dr. R. Lee. The communications with which he has at different times favoured us, and the lectures with which he is now enriching our journal, will have prepossessed them for any work from his pen; and "*Clinical Midwifery*" will not disappoint their expectations. The book is divided into eight chapters or "Reports." The first report consists

of observations on the present state of operative midwifery, and the histories of fifty-five cases of difficult parturition, in which the forceps was applied.

The second is on difficult labours from distortion of the pelvis, swelling of the soft parts, &c., in which delivery was effected by the operation of craniotomy.

The third report is on the induction of premature labour in cases of distortion of the pelvis, cancer of the gravid uterus, uterine and ovarian cysts, and tumors, &c. &c.

The fourth is on difficult labours from presentation of the superior extremities, nates, and funis.

The fifth is on the causes and treatment of uterine hæmorrhage in the latter months of pregnancy, with the history of thirty-six cases of placenta presentation.

The sixth report contains the histories of thirty cases of uterine hæmorrhage, in which the placenta had been detached from the upper part of the uterus.

The seventh is on cases of retained placenta.

The eighth and last is on labours complicated with puerperal convulsions. Dr. R. Lee's work will be consulted by every accoucheur who practises his art with the zeal which it merits.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medice tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

MEDICAL STATISTICS.

THE general principle of *ascertaining* facts is perhaps the most important to the progressive improvement of the art of healing; then follow the registering and the combining of those facts. The ascertaining of facts in the earliest ages, when the sick were placed in public thoroughfares to receive advice from the experienced, and the registering of these facts by means of votive tablets, enabled the Father of Physic to

carve out his great image of nosology, so dignified in form and so accurate in detail, and to place round this, his principal figure, some appropriate groupings in the form of therapeutic agents, hewing out of materials scattered and difficult of access, an object admirable to after ages, and bearing colossal marks of genius. This work, remarkable for symmetry of form, vigour of execution, and faithfulness of detail, is still the admiration and the model of the studious man of taste, and often serves as a rebuke to the flippancy of supposed inventors.

The tendency which leads to the combination of individuals for carrying out various objects, may almost be regarded as instinctive in man; so readily, so immediately, does he resort to association when any object of difficult and distant attainment is presented to his view.

But the ascertaining and registration of facts is a task which holds out little encouragement to the superficial and the careless. The most reasonable doubt as to the value to be calculated on from a large amount of statistical information, arises from the scarcity of those qualities which are required for its beneficial prosecution:—a scarcity absolutely great, relatively greater still; for facts, to be useful, must be very numerous. Half the truth is little better than a lie. There is no mischievous theory whatever that does not tell the truth in part; and the *fact* that Mrs. A—— and Mrs. B—— got through their ailments with Morison's pills, causes more evil than the death of a peeress, with the same aid, would neutralize.

It remains to be seen whether or no we have the *material* for raising up a body of accurate observers and patient recorders, in a profession which demands, for its successful practice, an especial degree of intelligence and

promptness; and where the very appearance of indecision is apt to be fatal to a reputation for cleverness. There are two or three points in which every individual may promote the good cause; and without stopping to inquire how far public men neglect their great opportunities, we wish to shew private practitioners, who, after all, have the conscience of the profession in their keeping, how they may best enlighten that conscience, and remove temptations to neglect its warnings, and to shrink from responsibility.

1st. Let every case we attend be registered. The form proposed by the Committee of the Statistical Society is not perhaps perfect, but is very excellent indeed; and, if only because the most commonly adopted at public institutions since the date of the circular issued by that Committee, is unquestionably the best. When modifications are found necessary, let them be discussed and agreed on. A decimal currency may be abstractedly better than our own, but every man will do well to keep his accounts in pounds, shillings, and pence, for the present.

2dly. Let this registration be done, *partly* at least, in presence of the patient; details may be filled up at leisure. Nothing is lost by this, even in the most exalted private practice. Those who have uniformly adopted it have in the end secured the confidence of their patients in the highest degree. This should not be misunderstood. It is not meant that a dull man, who laboriously registers every symptom, will succeed better than a clever man, whose practice in this respect is more off-hand, but that both the dull man and the clever man will succeed better with registration than without.

Where treatment has been carelessly conducted, patients are apt to attribute success to individual cleverness. This gives a manifest advantage to the

quack, who is not seldom possessed of that cleverness, and is of course more dexterous in the manner, and unscrupulous in the means, of turning it to profitable account. Failure in like manner is attributed to personal deficiency, producing loss of reputation to the individual; or if he be supposed to have his whole art actually at his fingers' ends, then the blame is laid on the deficiencies of our craft—to the manifest advantage, in this case also, of unscientific pretenders.

The practitioner who registers his cases with their treatment, gains a just and legitimate property in them, evident to the patient, who feels that a careful record of his case, and of the curative means which have already been employed, is deposited with his medical adviser, whom he therefore knows to be the best person to consult upon it in future. It is not surely too Utopian to imagine that some day a medical ledger may contain, not nauseating columns of the different sized phials emptied by the patient, with the details of their prices, "of no use to any one but the owner," but a record of nosological and therapeutic facts, grouped with judgment, tabulated for reference, and ready to form an additional layer in the solid edifice of inductive science.

In a consultation too, the junior practitioner could produce his notes, and enrich them with the experience of his senior: the respect due to each would be increased: diligence on the one hand, penetration and experience on the other, would be combined for the benefit of the patient.

There is a fear, perhaps, of reducing men of talent to the level of dull mediocrity, and some will feel about it, as the brave warrior did on the introduction of gunpowder;—his art of fence, and his personal bravery, gave him no advantage over every clown who could pull a trigger.

But let not the most brilliant and acute practitioner fear the consequences of a general adoption of the numerical method in recording accurately different modes of treatment; rather let him rejoice that his talents will have a wider field for their exercise. That invaluable tact which so distinguishes one man above another in circumstances of doubt and difficulty, and which seems to consist in the power of practically bringing to bear all the available knowledge, and energetically concentrating it on the most important points of a case, will always be a ground for preference, and a prime element of success. Every enlargement of the sure basis of facts increases the chance of a science being raised higher towards the pure regions of abstract truth. No number of years ever passes without some plausible theory being constructed, which excites much admiration, and seems to promise a speedy ascent to the much-desired heights; but, after a time, each in its turn is found to have been unsubstantial, to have melted away, and to be recognised only by the facts which it had contained, and which have settled down to form in their turn a substratum for other theories and for other facts.

There is, of course, some risk that an undue value may be ascribed to this numerical method, and that the theory of not theorizing may prove as delusive as any of its predecessors. To deny this would be to overlook the tendency of the human mind to make a bad use of all that is good. And it will contribute not a little to the prevention of such an evil consequence, if the business of observing and recording be undertaken with caution, reflection, and fore-thought, with a wholesome distrust of first results, and a willingness to go on diligently and cheerfully in the work of notation, during those tedious intervals which

will necessarily occur between the complete working out of different interesting problems. Something of the patient perseverance of the alchemist will be required—of that faith in the reality of the good sought for, and of that modesty which attributed so many failures in the search to the unworthiness of the seeker. If these mistaken men produced some most valuable substances, while toiling over their crucibles, under all the disadvantages of imaginations heated, and views distorted by theories and speculations no wonder, then, that after the great counterblast had been sounded by Lord Bacon, we find Hooke thus writing:—"The science of nature has been too long made the work of the brain and of the fancy; let it now revert to plain and sound observation, and let all intelligence be severely examined; let there be rigour in admitting, strictness in comparing, slowness in debating, and shyness in determining." But "this most diligent experimenter, who recorded his results with all that cautious sobriety which he advises," (as Mr. Brande tells, in his history of the origin and progress of chemistry,) was led by his genius to discard the favourite notion of an element of fire, a notion which seemed inseparable from the chemistry of his day, and to venture on a theory of combustion truer by two centuries than the "phlogistic theory," which for a time supplanted it; and for his chastened theoretical aspirations, he pleads thus apologetically:—"If ever I have ventured at *small conjectures* respecting the causes of the things I have observed, I beseech the reader to look upon them only as doubtful problems and uncertain guesses, not as unquestionable conclusions, or matters of unconfutable science." Such men, and in such times, need not, and do not, preface a course of lectures with a bonfire

made of the writings of their predecessors, or rivals. The modern school of chemistry (essentially one of weight and measure), has certainly not been deficient in brilliant theories. Our present searching examinations, stethoscopically, microscopically, and statistically pursued, are so many ways of interrogating nature. We are asking her a vast number of searching questions, to some of which, no doubt, within the next twenty years, we shall obtain categorical answers.

One most beneficial result to be desired and expected from judicious statistical inquiry is the keeping our profession in its proper relation as the adviser of the state, to be referred to with confidence on important questions of public health. We must be ready with our facts and figures when called upon to answer these questions, and they will be no less useful in private. No doubt, Mr. Farr's startling inference that the neglect of vaccination produces a mortality among children exactly equal to throwing two-thirds over London Bridge, has often been quoted with a beneficial effect on the prejudices of parents who would not have attended to more lengthened and persuasive disquisitions in favour of vaccination.

Some inconvenience will probably be felt from the comparisons unavoidably suggested between the success attending different methods of cure, different places, and different practitioners; some reproaches will be made; discredit will be attached, sometimes justly, sometimes unjustly, to individuals, and pain will be inflicted thereby; but in proportion to the faithfulness and fulness with which materials for commentary are furnished, will this unavoidable burden be adjusted—adjusted, as the Arab proverb has it, "on the march." To carry on the illustration, we would say, let each cheerfully take up his allotted share,

be it great or small, lest men have cause to exclaim—

“Alas for him that is gone, and has done no good deed.
The trumpet of march has sounded, and his burden is not yet bound on.”

ROYAL MEDICAL & CHIRURGICAL SOCIETY.

November 22, 1842.

DR. WILLIAMS IN THE CHAIR.

Account of a Case in which the Thigh was amputated during the Mesmeric State.
By W. TOPHAM, Esq. of the Middle Temple, and W. S. WARD, Esq. Surgeon.

JAMES WOMBELL, aged 42, a labouring man, of a calm and quiet temperament, had suffered, for a period of about five years, from a painful affection of the left knee. On the 21st day of June last, he was admitted into the District Hospital at Wellow, near Ollerton, Notts; no longer able to work, and suffering much pain. It was soon found that amputation of the leg, above the knee-joint, was inevitable; and it was eventually proposed that it should be performed, if possible, during mesmeric sleep.

In the first attempt to mesmerise him, which occupied me thirty-five minutes, the only effect produced was a closing of the eyelids, with that quivering appearance peculiar to mesmeric sleep; and, though awake and speaking, he could not raise them until after the lapse of a minute and a half.

My attempt the next day was more successful, and in twenty minutes he was asleep. From the 9th, I continued to mesmerise him every day, except the 18th, until the 21th of September, his susceptibility gradually increasing; so that, on the 23d, the sleep was produced in four minutes and a half. The duration of this sleep varied, continuing generally for half an hour; sometimes for an hour; and occasionally for an hour and a half. But, with two exceptions (attempts to converse with him), I invariably found him awakened, though without being startled, by the violent pain from his knee, which suddenly recurred at uncertain intervals.

After constantly mesmerising him for ten or twelve days, a great change was observed in his appearance. The hue of health returned; he became cheerful; felt much stronger; was easier both in mind and body; slept well; and recovered his appetite.

On the 22d of September he was first apprised of the necessity of an early amputation. The communication seemed almost

unexpected, and affected him considerably. I this day tried the experiment of mesmerising him against his will; proceeding by contact with the hands, charging him particularly to exert his mind to prevent my affecting him. During the process he occasionally glanced at those near him, moving his eyes as he felt inclined, and in twelve minutes and a half passed into mesmeric sleep.

On the morning of Saturday, the 1st of October, I again mesmerised Wombell, having done so the two previous days. This was done in the presence of Mr. William Squire Ward, of Wellow (the operator), and two other surgeons, in order that the previous mesmerism might tend, as I believed it would, to render his sleep deeper when again mesmerised for the operation; and also to satisfy them of the state in which he would be when that time arrived.

He slept an hour, and was roused by an attempt to converse with him. I then shewed them my power of affecting any one of his limbs, even when he was quite awake. At my request he extended his arms alternately. By making two or three passes over each, without any contact, I so trausfixed them that, from the shoulders to the tips of the fingers, they became as rigid and unyielding as bars of iron, not to be unbent, except by mechanical force powerful enough to injure the limbs; and yet instantly relaxing throughout, and dropping to his side, from the effect of my breath alone. His right leg was affected in the same degree; and relief from immediate pain was frequently afforded by making similar passes over the diseased one. Though the sensibility to pain was diminished in the limbs thus affected whilst awake, it was only during mesmeric sleep I found it totally gone.

At half-past one o'clock we proceeded to Wombell's room, to make the necessary arrangements. From the suffering inflicted by the slightest movement, it was found impossible, without needless torture, to place him upon a table. The low bed on which he then lay was therefore lifted upon a temporary platform. Ten minutes after being mesmerised, he was drawn, by means of the bed-clothes beneath him, towards the end of the bed. The movement, however, excited that pain which had so often aroused him before; and now it did so again. There was something quite excruciating in the suffering which the state of the knee produced; for I had seen him, whilst in mesmeric sleep, pricked to some little depth in other parts of the diseased limb, without being disturbed or conscious of it. To preclude the necessity of any further movement, his leg was now placed in the most convenient position which he could bear. Shortly afterwards

he declared that the pain had ceased; and I again mesmerised him, in four minutes. In a quarter of an hour, I informed Mr. Ward that he might commence the operation. I then brought two fingers of each hand gently in contact with Wombell's closed eyelids; and there kept them, still further to deepen the sleep. Mr. Ward, after one earnest look at the man, slowly plunged his knife into the centre of the outer side of the thigh, directly to the bone; and then made a clear incision, round the bone, to the opposite point, on the inside of the thigh. The stillness, at this moment, was something awful: the calm respiration of the sleeping man alone was heard; for all other seemed suspended. In making the second incision, the position of the leg was found more inconvenient than it had appeared to be; and the operator could not proceed with his former facility. Soon after the second incision, a moaning was heard from the patient, which continued, at intervals, until the conclusion. It gave me the idea of a troubled dream; for his sleep continued as profound as ever. The placid look of his countenance never changed for an instant; his whole frame rested, uncontrolled, in perfect stillness and repose; not a muscle or a nerve was seen to twitch. To the end of the operation, including the sawing of the bone, securing the arteries, and applying the bandages,—occupying a period of upwards of twenty minutes,—he lay like a statue. Soon after the limb was removed, his pulse becoming low from the loss of blood, some brandy and water was poured into his throat; which he swallowed unconsciously. As the last bandage was applied, I pointed out, to one of the surgeons and another gentleman present, that peculiar quivering of the closed eyelids already alluded to. Finally, when all was completed, and Wombell was about to be removed, his pulse being still found very low, some *sal volatile* and water was administered to him; it proved too strong and pungent, and he gradually and calmly awoke.

At first, he uttered no exclamation; and, for some moments, seemed lost and bewildered: but, after looking round, he exclaimed, "I bless the Lord to find it's all over!" He was then removed to another room; and following immediately, I asked him in the presence of those assembled, to describe all he felt or knew, after he was mesmerised. His reply was, "I never knew anything more; and never felt any pain at all: I once felt as if I heard a kind of crunching." I asked if that were painful? He replied, "No pain at all! I never had any; and knew nothing, till I was awakened by that strong stuff" (the *sal volatile*). The "crunching," no doubt, was the sawing of his own thigh-bone. He was left, easy and comfortable; and still found so, at nine

o'clock that night; about which hour, I again mesmerised him (in a minute and three quarters), and he slept an hour and a half. I may further add that, on the Monday following, the first dressing of his wound was in mesmeric sleep. Of this dressing, usually accompanied by much soreness and smarting, he felt nothing; slept long after it was completed; was ignorant of Mr. Ward's intention; and, after awakening, remained unconscious of its having been done.

[The preceding is by Mr. Topham; what follows is from the pen of Mr. Ward.]

The case to which the attention of the Society has been already called, was one of very extensive ulceration of the cartilages of the knee-joint, of four and a half years' standing, the consequence of neglected inflammation of the synovial membrane, produced by injury, which was treated by a quack in the first instance, but did not come under my own notice until about three years before his admission into the District Hospital, at Wellow; when, supposing ulceration to have commenced in the cartilages, I ordered absolute rest, and the usual treatment; which was only adhered to for ten days, when, in spite of every remonstrance on my part, he returned to his ordinary employment (an agricultural labourer), in his still crippled state.

He then fell into the hands of other practitioners, whose discipline was less rigid, and whose prognosis was more sanguine than mine. I frequently met him, and occasionally warned him of the eventual loss of his limb if he persisted in using it. His last fair prospect was a promised cure by cupping; but this having produced no relief, he applied for admission into the hospital. At this time the disease had far advanced; the slightest motion of the joint was attended by the most excruciating agony; his nights were almost wholly sleepless, in consequence of the painful startings of the limb; his pulse weak and rapid; his face constantly marked with a hectic flush; his tongue foul, and appetite gone. He was now confined to his bed, but could not bear a horizontal position. The joint was supported by a light splint; poultices, fomentations, &c. were applied; attention paid to his general health; opiates, quinine, wine, &c., prescribed to get him into a fit state for the operation (which I deemed inevitable), without any apparent benefit; but, on hearing that Mr. Topham was coming into the neighbourhood, I determined to request him to try the effects of mesmerism upon him, with a view not only of tranquillising the system prior to the operation, but, if possible, to procure such a degree of insensibility to pain as to render the man unconscious of the operation

itself; having long desired to see this accomplished, as the "summum bonum" of mesmerism.

I was, however, obliged to leave home from indisposition at this period, but daily received reports of the progress made upon my patient; and on my return, on the 27th of September—about three weeks after the commencement of the mesmerism—I was as much astonished as I was delighted, to observe the improved condition of the man. He had, now, much more the hue of health; his nights were more quiet and tranquil; his appetite had returned; and, in fact, such was his state, that had I not known the previous history of the case, much doubt must have arisen, in my mind, as to the propriety of immediately amputating the limb. It is true, there was still the pain, on the slightest movement of the joint; and still some of the same painful startings at night; but he no longer appeared to be suffering in his general health, which, on the contrary, was greatly improved: nevertheless, I felt assured, notwithstanding all this in his favour, that there was too much disease to admit of a final recovery.

As I had quite determined upon not attempting to remove the limb while the patient was under mesmeric influence, unless I was convinced of its safety, and had opportunities of seeing him in that state; and, moreover, not without the man's own full concurrence; on the 29th, I requested Mr. Topham to mesmerise him; when I was delighted to find his susceptibility so great. When asleep (if I may use the term), his breathing was unaltered; his pulse tranquil, and about 80; his waking was slow and gradual, and without the least start; and I found he was insensible to the prick of a pin.

Under such circumstances I saw no grounds for fear or hesitation; and having obtained the patient's consent, or rather at his own urgent request, I fixed the following Saturday, 1st of October, for the performance of the operation.

The patient (as has been already stated) was lifted, with his bed, upon a platform; and, although he was considerably excited by hearing the cries of another patient, upon whom I had been performing a tedious and painful operation in an adjoining room, he was soon put into mesmeric sleep; but as I wished him to be placed in the usual position, with the limbs extended over the end of the bed, an attempt was made to draw him down with the bed-clothes; but this occasioned so much pain as to awake him. I was now somewhat embarrassed, as his position on the bed, with his extremity lying in close contact with it, was so very unfavourable to the operator; but, having proceeded thus far, I was unwilling to mar the first attempt

at lessening the horror and pain of a capital operation; although, I must confess, I was by no means sanguine of success. The patient was again put to sleep; previously to which a surgeon present raised the limb about two inches from the mattress, by resting the heel upon his shoulder and supporting the joint with his hand; promising also, if the man should awake, instantly to draw him down, so as to allow the leg to extend beyond the edge of the bed.

In a few minutes, Mr. Topham said he was quite ready; when, having adjusted the tourniquet (the very unfavourable position of the patient precluding the possibility of otherwise compressing the artery), I proceeded to perform the operation, as has been described. Having made the anterior flap, without the slightest expression of consciousness on the part of the patient, I was under the necessity of completing the posterior one, in three stages. First, by dividing a portion of the flap on the inside; then a similar portion on the outside. This proceeding (which of course was far more tedious and painful than the ordinary one) was rendered necessary, to enable me to pass the knife through, under the bone, and thus complete the whole; as I could not sufficiently depress the handle to do so, without the two lateral cuts.

Beyond what has been already so well described by Mr. Topham, I need only add, that the extreme quivering or rapid action of the divided muscular fibres was less than usual; nor was there so much contraction of the muscles themselves: I must also notice, that, two or three times, I touched the divided end of the sciatic nerve, without any increase of the low moaning described by Mr. Topham; and which, to all present, gave the impression of a disturbed dream.

The patient is doing remarkably well, and sat up on Sunday last to eat his dinner—just three weeks from the operation; and he has not had a single bad symptom: none, even, of the nervous excitement so frequently observed in patients who have undergone painful operations, and who have suffered much previous anxiety in making up their minds.

On dissection of the joint, the appearances fully verified my diagnosis. The cartilages of the tibia, femur, and patella, had been entirely absorbed, except a much-thinned layer, partly covering the patella. There was deep carious ulceration of the exposed ends of the bones; and especially on the inner condyle of the femur, which had wholly lost its rounded shape. Some coagulated lymph was effused upon the surface of the synovial membrane, in several places; and the joint contained a certain quantity of dark-coloured pus.

After the reading of the preceding case (our account of which is taken from the report published by the parties themselves), a considerable number of the members expressed their opinions; but we can only make room for what was said by one or two.

Mr. Alcock argued that the circumstance of no pain being expressed, by no means proved that none was felt, and mentioned the case of a patient of his own, who smoked his pipe, with the most perfect composure, during the whole time of his performing a capital operation upon him.

Sir Benjamin Brodie alluded to the case of the sleeping boy, recorded in the Philosophical Transactions by Dr. Oliver, and who suffered pins to be thrust under his fingernails, and various other kinds of torture to be inflicted, without giving the slightest sign of pain. He also mentioned the case of a distinguished physician of the present day, on whom he had operated for strangulated hernia, and who had shewed such perfect composure as to ask questions about the various steps of the operation, handling the instruments, and conversing with perfect tranquillity while the operation was being performed; the only indication of suffering having occurred when Sir Benjamin touched a nerve which was exposed. After alluding to some analogous cases, he expressed his approbation of the report of the French Academy, to the effect that animal magnetism was a complete delusion, and added his concurrence on what had been said by one of the former speakers—namely, that the paper ought not to have been admitted by the Council.

Mr. Coulson, Dr. Moore, Dr. Blake, Mr. Bransby Cooper, Mr. Liston, Dr. Marshall Hall, and some other gentlemen, expressed themselves as disbelievers in mesmerism.

Dr. Mayo expressed his opinion that there existed something more than mere indifference to pain in what was called mesmeric phenomena, and mentioned that he had thrust a pin into the arms of one of the girls O'Key, without her shewing any sign of pain, although she could not possibly have known beforehand what he was about to do.

Dr. Elliotson spoke rather fully upon the subject of mesmerism, and explained his own opinions in its favour, denying the applicability of Sir Benjamin Brodie's remarks. He argued that cases such as he adduced were only instances of insensibility to pain, and that such were not uncommon. In illustration of his meaning he referred to the case of a female, which occurred in the Royal Infirmary at Edinburgh in 1830, the skin of whose hands was lacerated and torn while she was in a state of insensibility, and without her feeling it in the least; but he did not regard such instances as bearing upon the question. He expressed his dissent from the report of

the French Academicians, and, on sitting down, declared his determination to maintain his opinion, and pursue his researches on the subject of mesmerism, regardless of the ridicule which might be heaped upon him for doing so.

We have received a letter from one of the gentlemen present, and which we subjoin.

To the Editor of the Medical Gazette.

SIR,

I WAS present at the meeting of the Royal Medical and Chirurgical Society, on last Tuesday evening, and was one of those who regretted that any fellow of the society should have been so good-natured to the authors of the very silly paper on Mesmerism, as to comply with their wishes, by presenting such a paper to be read at one of our meetings.

The unfortunate patient whose case was recorded, who *moaned during the operation, and heard a crunching during the sawing of the bone*, evidently felt quite enough; and gave as much sign of feeling it, as many patients do under similar circumstances. And it requires no very deep knowledge of human nature, to imagine various motives which might induce him to express himself as he did afterwards.

It is rather remarkable that it should have occurred to no one present to mention the case of a woman whose breast was amputated, some years ago, in Paris, by M. Cloquet, while she was (as it was supposed) in a state of mesmeric stupor. This woman was believed to have been insensible to pain during the operation; and was a better actor than the man mesmerised by Mr. Topham, as she did not even moan. Some considerable time afterwards, however, while dying of an internal complaint in another hospital, she confessed to the nurse that the whole had been a cheat; that she had experienced pain during the operation, like other persons, but had sufficient command over herself not to shew it.—I am, sir,

Your obedient servant,

F.R.M.C.S.

CLINICAL LECTURES,

Delivered at St. Thomas's Hospital,

By SAMUEL SOLLY, Esq., F.R.S.

Assistant-Surgeon, and Lecturer on Clinical Surgery, at St. Thomas's School.

LECTURE II.

On Diseases of the Spine.

IN my last clinical lecture I dwelt much on the physiology of the spine as a centre of support, showing upon what structures its strength depended, and how deformity should be prevented, and how its progress

should be arrested, when your advice is sought in the early stage of the disease. Your attention shall be directed to the treatment of more confirmed cases of distortion, when we have some patients in the hospital to illustrate my observations. The spinal column is interesting to the surgeon not merely as a bond of union between the different portions of the skeleton, held together and supported by numerous muscles and ligaments, but from the fact that it contains within its tube that important centre of the nervous system, the spinal chord. This relation of the column to the cerebro-spinal axis should always be borne in mind when you are called upon to treat any of the diseases to which it is liable, but it is especially important in connection with the spinal diseases of which the following case is an illustration.

William Dickerson, æt. 21, farmer's labourer, from Cambridgeshire, was admitted into St. Thomas's Hospital, Aug. 22, 1842, with posterior angular curvature of the spine at the ninth dorsal vertebra.

States, that until six months ago he had no signs of disease, or curvature, whatever. He first noticed a sharp aching pain across the hips and loins, increased by coughing and percussion; at this time he was exposed to wet and cold at his work, though not more than farming labourers are generally; he never had rheumatism, but he has cough at the present time; he does not remember having strained or hurt himself in any way.

August 2d, 1842.—The spine presents no lateral deviation, but at the ninth dorsal vertebra there is a considerable projection posteriorly. He suffers acutely if this point is tapped with the hand.

There is no paralysis of the legs, but they are subject to occasional twitches.

Some cough, attended with bronchial expectoration.

General appearance tolerably healthy; appetite good.

Hydr. c. Creta, gr. ij.; Conii. gr. iij.
o. n.; Moxa lumbis.

Sept. 15th.—C. Cruentæ, ad 3vj.

21st.—Linctus pro tussi.

22d.—Moxa Lumbis, Hirudines xij. lumbis.

26th.—C. Cruent. Lumbis ad 3vij; Moxa Rep.

Nov. 1st.—C. Cruent. ad 3vij.

He is now free from pain in his back; he can bear it to be tapped without suffering; but if he coughs or sneezes he has a shooting pain down from the loins. He still, at times, has a little numbness down the legs, but not so much as he had; his countenance and general health are good.

You will immediately perceive that this

case illustrates one of the grand divisions of spinal diseases into which I stated they were usually divided: viz., that deformity which is occasioned by actual disease of the bones of the vertebræ. We must now consider how this disease commences, and whether it is similar to other diseases to which our frames are subject.

Bone is liable to be affected with the same kind of diseases as the soft parts; inflammation and its consequences, ulceration, supuration, gangrene, &c., though the difference of texture modifies the progress of the disease, and appearance which it presents. Different terms have been employed in designating its diseases: thus, ulceration is called caries, and gangrene necrosis, &c.

When the ulcerative process attacks a bone, it is not easily arrested, and a considerable portion of bone is usually destroyed before the ulcer heals.

The texture of the bone which has been removed by this process is never entirely filled up, and the vacant space remains. Supposing, then, caries to have attacked the body of one or more vertebræ, the consequence will be that a considerable gap will be formed in the anterior portion of the column, depriving it of its firmness and solidity.

If you look at this beautiful preparation of caries of the spine, you will immediately perceive the cause of angular curvature. The bodies of the vertebræ have ulcerated, and thus allowed those above and below to approximate anteriorly; the spinous processes are consequently separated, and form the angular projection which you see here, and which can always be detected during life, as in the case just related.

In regard to your diagnosis of caries of the vertebra in such cases as the present you cannot easily err, for here the disease had extended so far as to produce the angular curvature I have described. But it sometimes happens that the first indication of caries of the spine is partial paralysis of some of the muscles of the extremities, unaccompanied with any spinal deformity. In such cases it is extremely important to detect the cause of such paralysis—whether it is dependent on lesion of the spinal cord or brain, and if of the cord, of what portion. Generally speaking, if you carefully examine the spine from the cranium to the sacrum, tapping gently the spinous process of each vertebra, you will discover the seat of the disease. But this plan does sometimes fail. Mr. Copeland recommends the application of a sponge wrung out of hot water, and he relates a case of caries of the spine which he detected in this way when every other had failed. Sir B. Brodie observes, that there are cases “in which there is no pain in the spine whatever from the first access of the

disease to its termination," and others, in which the disease has been supposed to be cured, the patient not having experienced any pain for two or three years, but in whom, after death, the bodies of the vertebrae were found to be still in a state of caries, and an abscess, containing not less than half a pint of matter, connected with them.

Supposing, then, that you have ascertained the existence of caries of the spine, even though it be prior to the existence of deformity, it is a matter of no little importance to you to learn whether the disease commences in the osseous or the ligamentous tissues of the column. It is not often that we have the opportunity of examining these cases in the very early stages—before, in fact, the deformity has commenced—which too frequently is the first intimation we receive of the existence of any malady at all. In this preparation you have the opportunity of observing one form of the disease in its very early stage. The anterior ligament of the spine exhibits marks of inflammation; it is separated from the bone, and fibrinous matter deposited between them: this inflammatory action is the precursor of ulceration of the vertebra; and thus, in some instances, does the disease commence in the ligamentous, not the osseous tissue.

The researches of Sir B. Brodie shew that the ulcerative process does not invariably commence in the bone, but occasionally in the fibrous intervertebral cartilage. "I have," says this author, "in some instances, found the intervertebral cartilages in a state of ulceration, while the bones were either in a perfectly healthy state, or merely affected with chronic inflammation, without having lost their natural texture and hardness; while in others it has been manifest that the original disease was the true scrofulous disease of bones."

When the disease commences in the cartilage it extends to the bone by simple caries or ulceration, and such cases are much more likely to terminate favourably, that is, with ankylosis, than the scrofulous disease of the bone.

It is therefore important, if possible, to distinguish them in the early stage, both in regard to your treatment and your prognosis. It would be incorrect to assert that this distinction can always be made; but I think the following points may assist you in forming your opinion. You do not meet with decided scrofulous disease of the bodies of the vertebrae, without tolerably decided indications of a scrofulous diathesis, as exhibited by the general appearance of the patient, and symptoms of the disease in other organs; whereas direct injury, such as a forcible twist of the spine, occurring in a person of good general health, without any strumous taint, though deficient in general

power, may lead to inflammation of the anterior and posterior ligaments of the spine, or the intervertebral substance, which, if unchecked, goes on to ulceration, not merely of the fibro-cartilages, but of the bones themselves. Such serious consequences do not often follow strains in strong healthy persons, but only in individuals of lax muscular fibre.

This severe injury of the ligamentous connections of the vertebral column takes place in consequence of the spinal muscles, whose office I described in my former lecture, under the title of intelligent ligaments, not performing their duties efficiently. From deficient muscular power a greater strain is thrown upon the spinal ligaments than they can bear. You must not, then, confound inefficient muscular action, arising from general want of power, with the strumous or scrofulous diathesis. The following case, which I saw at home, on Thursday last, the 3d instant, illustrates the kind of injury which is very likely to lead to disease of the intervertebral substance if it is not checked.

Rebecca Warland, æt. 42, married woman, wife of a brewer, has always lived well, but not to excess; appearance rather delicate, but not unhealthy; has had seven children, and five living, the youngest seventeen months old; she nursed until it was five months old. Applied to me at home on account of a pain in her back and loins, which is constant, and a most distressing sensation on stooping. She attributes her present symptoms to a fall, exactly a week ago, in coming down stairs, when she slipped, and falling partly over the bannisters, twisted her spine. She suffered most acute pain at the time, which has never left her altogether since, but has rather increased.

She feels a twitching of the legs while walking, and a catching in her back, which she says causes her to draw up her right leg. The pain she experiences in her back is principally on the right side. The spine is throughout tender to the touch; but she suffers acutely if it is tapped over the fourth lumbar vertebra, which was the exact seat of the pain at the time of the accident. As she is falling off to sleep at night, she is awoke with twitchings and catchings of the legs and back part of the head, and when thus roused, she is not collected immediately on awaking, as she always was previous to the accident, but is confused and bewildered. In the day-time, if she stoops her head she feels giddy and loses her memory. Tongue white, and slightly furred; pulse 68, soft; bowels as usual, rather confined. Ordered—

Cal. c. Rhei, gr. xv.; Cuc. Cruent. Lum-
bis ad ʒviii.

It is evident from the serious effect produced upon the nervous system, which has

even extended from the spinal cord up to the brain, how severe a twist the spinal column itself must have received. There must have been a temporary and partial displacement, though probably only momentary, or the cord, which is so beautifully protected, could not have been so much injured. The cause appears slight in comparison with the lesion produced; and we can only account for it on the principle before adverted to, namely that the muscles, as supporters of the columns, did not faithfully perform their duty, either from want of sufficient power, or from their being taken unawares before they had time to contract efficiently.

I think it right to employ the cupping-glasses in these cases in the first instance, as being more efficient in the acute stage of inflammation, and less painful than the moxa. This patient has been much relieved by these measures, and the symptoms of injury to the cord very much alleviated. I cannot impress too strongly on your mind the necessity of treating such cases actively at first, and watching them carefully afterwards.

I have two cases in my mind's eye at this moment, in which partial paralysis followed from what I must again designate as sprain of the spine. The one occurred to a steward on board a vessel, as he was lifting some very heavy trunks belonging to a passenger; the other to a carpenter. The first case was in private; but the subject of the latter was a patient in Henry's Ward, and as his case is short I will read it to you.

Henry Lambton, æt. 29, married man, three children, by trade a carpenter; states that he has always had good health; appearance not strumous; was admitted into Henry's ward, January 25th, 1842, with partial paraplegia.

He is scarcely able to walk, catching his toes against the ground, and dragging his limbs as he supported himself with a stick; without which, indeed, he could not stand. His legs and thighs feel numb; the left extremity is rather the worst, both in respect to sensation and motion. He has not now, nor ever had, any pain in his head. His general health is good.

His account is, that one year previous to his admission into the hospital, he strained his loins lifting a very heavy weight. He felt at the time a considerable pain in the lower part of the back, from which he has never been entirely free since. He had medical advice at the time, and was cupped and blistered, but he gradually lost the use of both his limbs in about four months from the time of the accident.

Jan. 27th.—I ordered him Hydr. c. creta, gr. ij. om. nocte. Two moxas, one on each side of the lumbar portion of the spine, where he experienced most pain on pres-

sure. Strict confinement to the recumbent posture.

March 9th.—Much better, both as regards sensation and motion. Mouth very tender. To take the Hydr. c. creta, gr. j. instead of ij. The issues discharge very little. Ordered two fresh ones.

19th.—Can now get out of bed without assistance, which he could not do when he came in. The numbness of the extremities is nearly gone, and he can walk without any dragging of his limbs. He does not walk firmly, like a strong man, but he improves after he has been up some time.

Soon after the date of the last report, he got impatient of the confinement, and went home. He returned again in about two months, much worse; but as he refused to keep the recumbent posture, he was dismissed.

In this case there was no irregularity of the spinous processes, or indication of disease of the osseous tissue. That a very decided change had taken place in the vertebral canal was very evident from the paralysis, caused in all probability by pressure on the cord from fibrinous deposit, the result of chronic inflammatory action of the intervertebral substance, extending to the ligaments. The rapid improvement under the influence of mercury and the counter-irritation of the moxa, demonstrates that the cord could not have been damaged by the accident, but only compressed by some matter which afterwards became absorbed. I have no doubt that the termination of this case, in consequence of the man's obstinacy, will be caries of the spine, angular curvature, and permanent paraplegia.

When disease of the bodies of the vertebræ is not the consequence of simple inflammatory action, by whatever cause such action may be set up, it is occasioned by scrofulous disease. This beautiful preparation, exhibiting its existence in the sacrum and last lumbar vertebra, taken from a man who died in the hospital during the summer, was produced by a direct blow on the part. He fell on board a ship from the main-top upon the deck—a height of about thirty feet—striking the sacrum. The accident occurred just three years before his death, during which time he frequently partially recovered: the immediate cause of his death was phthisis. You have frequently during the present season seen the effects, in different parts of the frame, of scrofula—this dreadful scourge of the human race: sometimes attacking one joint, sometimes another; sometimes arising spontaneously in the system, and sometimes consequent upon severe local injury.

Ulceration of the soft parts is always accompanied by suppuration; but not so caries of the bone. It would, however, ap-

pear that suppuration more frequently follows the caries which commences primarily in the bodies of the vertebræ than that which commences in the ligamentous tissue. The extent to which caries will go on in the latter case, without the formation of matter, is quite extraordinary. Sir Benjamin Brodie says: "I have known as many as three bodies of vertebræ destroyed, and the disease to have lasted many years, without matter having been formed; a fortunate circumstance for the patient, as the chance for his recovery is much greater under these than it would have been under opposite circumstances. It does not follow that because no abscess appears that therefore none exists, for they will lie dormant sometimes for years." The same surgeon relates two cases, in one of which there was disease of the loins, and an abscess presented itself in the groin at the end of eight years; and in another, in which the disease was situated in the dorsal vertebra, the interval was sixteen years.

The course which the pus takes towards the skin, after its secretion, varies very considerably. Sometimes it presents on the sides of the vertebræ posteriorly, as in the case from which this cast was taken. The subject of it you saw on Wednesday among the out-patients. Sometimes, I think most frequently, it follows the course of the psoas and iliacus muscles towards the groin, when it presents itself as a firm elastic swelling, not unlike an adipose tumor; for the fluctuation is very indistinct, in consequence of the quantity of loose adipose tissue in this situation, and the firm aponeurotic covering it receives from the iliac fascia.

As these remarks have led me to the subject of psoas abscesses, it may be well to observe, that, you must not consider these abscesses as invariably the result of diseased vertebræ. We had a case in William's ward a few weeks ago, in which there was an extensive collection of matter in the iliac fossa produced by inflammation of the lumbar and iliac fascia, excited by cold and wet. As I have no doubt we shall have similar cases again in the hospital, I shall not now detain you on this branch of the subject.

In caries of the cervical portion of the spine, when pus is secreted, it will find its way in various directions between the muscles of the neck. It has been known to burst into the pharynx. Sir Benjamin Brodie states that he has seen one case in which it burst into the theca vertebralis, and the whole cord, from its origin to its termination, was bathed in pus.

The most serious cases of caries of the cervical vertebræ are those in which the odontoid process of the second vertebra has been the seat of the ulceration. There are

two or three cases on record in which the consequence was the sudden giving way of that process, which, allowing the head to fall forward, the medulla oblongata, or respiratory centre, was crushed, and instant death followed. Sometimes, fortunately for the patient, the inflammatory action leads to a more favourable result in the ankylosis of the two bones, as you see in this preparation.

Prognosis.—It is extremely necessary that you should be very cautious in your prognosis regarding the termination of all cases of caries. Your best guide, in regard to prognosis, in those cases in which there has been angular curvature, is to ascertain whether ankylosis has taken place or not; for if true angular curvature has once existed, it must have been caused by the absorption of the bodies of one or more of the vertebræ; and the substitution for such deficiency, experience teaches, is the soldering together, by bony deposit, the healthy bones above and below the seat of the original disease. This, of course, produces unnatural, though, under the circumstances, providential rigidity of a portion of the column. Since the commencement of this session you have seen two or three cases of ankylosed angular curvature of the spine: they have not been retained in the house, because surgery could not rectify the existing deformity, which our knowledge of the pathology of these cases teaches us it would be madness to attempt.

You may, therefore, as a general rule, feel satisfied that you have effected a cure if the patient is completely relieved of the pain in his back, and at the same time that the posterior projection is less, the rigidity of the column in that situation is unnatural and complete.

With regard to the length of time required to effect ankylosis, it is extremely difficult to state it. One of our best authorities considers that it is seldom effected under six months, and that most frequently it is necessary to retain your patient in the recumbent posture a year, or a year and a half.

When caries occurs in the lumbar vertebræ, the disease will often go on to the formation of abscess without any deformity of the spine, for the bodies of the lumbar vertebræ are so wide and large in every direction, that the absorption is seldom sufficient to cause them to fall forwards.

You will remember a man in William's ward, who had been a patient in the house for nearly twelve months, with lumbar abscess, which burst posteriorly. Now there was no deformity of the spine in this case, but there was great tenderness over the spinous processes of the third and fourth lumbar vertebræ; and I am inclined to

regard it as a case of caries of these vertebrae. I am supported in such a supposition from the extreme rarity of lumbar abscess independent of caries of the spine. From the greater length of the spinous processes in the dorsal region, and the comparatively small size of their bodies, you will readily understand that a much smaller amount of mischief to the bodies would necessarily produce considerable angular curvature.

Treatment.—In all cases of angular curvature entire rest is absolutely necessary; and this must be continued for some time; seldom less than four or five months, and often for a year, or a year and a half. The exact position in bed must vary with circumstances: as a general rule, that which is easiest to the patient is the best; and the lateral position will frequently be found so, taking care to support the back with pillows that are fixed so that they cannot be pushed away. In other cases it has been found desirable to place the patient on his face; and there is a very good convex bed for that purpose contrived, over which the patient lies.

In determining the position in which you place the patient, you must always remember that you must not attempt to correct the deformity; that the maintenance of the curve, and not its obliteration, is the thing to be sought for.

You must be guided in your choice of medicines by the fact of whether the disease appears to be strictly the consequence of a scrofulous diathesis, or of local inquiry—whether it is accompanied with paralysis or not. If you have a scrofulous diathesis to contend with, you must avoid mercury, and give the various forms of iodine in combination with sarsaparilla, and when these disagree with the stomach vary them with quinine, steel, &c. In some cases, but they are rare, there is sufficient indication of inflammatory action following local injury to justify you in the use of mercury in small doses. In cases of paralysis you cannot often get on without it, but your doses must be small; such as a grain or two at the most of hydrar. c. creta at bed-time. This mineral you give with the view of promoting absorption of that which is pressing on the cord, and producing paralysis. The following case will illustrate the efficacy of these measures, and teach you never to be discouraged in your treatment, though the recovery may proceed extremely slow, and sometimes even appear to stand still for a period altogether. When you have pushed the use of mercury even in these small doses as far as you consider consistent with the general strength of the patient, which must of course always be strictly watched, you may then prescribe iodine in doses commencing with half a grain, and going up to two grains,

to promote the further action of the absorbents. One word upon local treatment, and then I will read the case I have adverted to. The best counter-irritant is the oldest, that which was first recommended by Mr. Pott, I mean the moxa. You should not make them very large; about the size of a shilling is the best: never make more than one at a time: even if you intend, and it is generally necessary, to have two, do not keep them open more than three weeks or a month; heal them, and make fresh ones in the neighbourhood. In very young children, as in this case before you, I find the tincture of iodine extremely efficacious, and less exhausting than the moxa. This child, Henry Warden, was a year and a half old when he was brought to me about three months ago: he then had angular curvature about the sixth dorsal vertebra, and his general appearance was so wretched, from emaciation and pallor, that I never anticipated any favourable results. But you now see the child a healthy, ruddy, plump little fellow. The treatment has been simple—attention to the bowels, the administration of the tinctura cinchona internally, and the tincture of iodine to the back.

Rebecca Young, æt. 21, fair complexion, blue eyes, rather strumous appearance, was admitted into St. Thomas's Hospital in a state of complete paraplegia. She had neither feeling or motion below the sixth dorsal vertebra, which projects posteriorly, and is very tender on pressure. Parents healthy; live at Felstead in Essex; believes it to be a damp situation in winter. She cannot account for the disease; has always lived well, never carried heavy weights, or has she been in the habit of carrying children. She thinks that it must have been coming on for about five years, as she constantly suffered from pain in her back; on one occasion she felt a "*crick*" in her back, and from that time got gradually worse, and she was quite paralysed about six weeks previous to her admission, which took place on the 23d of March, 1841.

When I saw her on the 26th, I ordered her a purge of cal. c. jalap; which brought away some solid and scybalous faeces. This required to be repeated frequently, and had the effect of removing enormous masses of feculent matter.

As soon as the bowels were thoroughly evacuated, I ordered her a moxa on each side of the sixth dorsal vertebra, the situation of the angular curvature. On the 19th of April, I ordered two grains of iodine, to be taken three times, with the hope of promoting absorption of the deposit, which by its pressure was producing the paralysis. I was afraid that her constitutional powers would not be able to bear the effects of mercury, which was contra-indicated by her scrofulous diathesis. On the 22d, I increased it to

three grains; May the 3d, to three and a half; and on the 11th of June, to four grains. During this time there were gradual symptoms of improvement, which encouraged me to persevere. And it was interesting to observe the way in which the healthy state was gradually arrived at: first there were slight crampy feelings in the limbs; next twitching and catching; and afterwards decided convulsive involuntary movements.

On the 21st June another moxa was applied a little lower down the spine. On the 26th I ordered her meat daily, instead of the usual house allowance, which is meat four times a week.

On the 30th another moxa: during this period the bowels continued very sluggish, and she required repeated doses of castor oil.

Sept. 30th.—Some slight power of raising her legs, but still very imperfect, and scarcely any improvement in sensation.

Mr. Tyrrell now thought it a good case for trying strychnine, and ordered her the 12th of a grain three times a day: thus, Strich-nine, gr. i.; Tinct. Aurant. ʒiiss.; sumat. cochl. min. j. ter die.

Nov. 1st.—This was increased to the 8th of a grain: under this medicine she decidedly progressed, and recovered some sensation: at first she experienced shooting pains down the leg, like what is vulgarly called pins and needles; after a little while she suffered more decided pains, and as these subsided she began to feel the touch of the finger bluntly at first, but more acutely afterwards.

Dec. 6th.—The strychnine now began to act too powerfully, producing general convulsive twitching, and it was therefore abandoned.

Feb. 24th, 1842.—As she seemed a good deal depressed, and her general power rather failing, I ordered porter one pint, and a chop, daily. Her position in bed for the first three or four months was on her face, with very short intervals of change.

March 14th.—I ordered her the mixture, iodine and gentian, continuing the meat, and porter. This medicine was continued until the beginning of May, when her general health having much improved, but not the condition of the nervous system, on the 26th of this month I ordered her Hydr. c. Creta, gr. i. om. nocte. From this time her progress, though slow, was very decided, and on the 2d of August she was presented, and left the hospital able to walk about with the assistance of a stick, with perfect sensation and power of controlling and directing the motion of her limbs. Her spinal column presents the appearance presented in the diagram; namely considerable posterior angular curvature at about the 8th dorsal vertebra, the effect of which on the figure is almost counteracted by a full bowing forwards of the lumbar region of the spine;

so that when she is standing, there is not any very marked deformity, and she maintains the erect position very well: her stature is shortened, but not bent forwards.

Remarks.—This case is interesting in many points: first, as regards the nervous system, it shews that though the scrofulous disease of the bodies of the vertebra, which caused an angular curvature that must ever remain, had so far encroached on the spinal canal as to press upon the spinal cord and obliterate its functions entirely for almost two months, that, nevertheless, it still retained its integrity, and recovered its function, when that pressure was removed. It was to promote this result that I ordered the iodine; which I preferred to mercury in the first instance, for reasons stated above. The moxa, I believe, had the effect of assisting this result.

It would also appear that the strychnine had some effect in restoring the natural functions of the posterior column, more especially after the pressure had been removed, but still it did not effect a complete cure. This I believe was ultimately accomplished through the agency of minute doses of the Hydr. c. Creta, continued for some time, which I then no longer feared to administer, as the disease of the bodies of the vertebrae was evidently arrested, and her general health very much improved.

You will now, I trust, thoroughly understand the pathology of the case of William Dickerson, and the principles of treatment which have been pursued. So far they have been successful, but anchylosis has not yet taken place, and our great difficulty will be to persuade him to keep the recumbent posture, now that he is free from pain, until it is accomplished.

METHOD OF DETECTING ADULTERATION IN THE EXPRESSED OILS OF COMMERCE.

To M. Heidenreich, pharmacien of Strasbourg, it was proposed to decide, whether the adulteration of different oils could be ascertained by definite chemical tests. It then became an object of research with him to find out some method of proceeding which would enable those who are not *au fait* at chymical experiments to detect these adulterations, by furnishing some accurate characteristic test which might be employed without much trouble, or requiring nicety of manipulation; and he therefore directed his attention to the three following series of experiments:—

1. *By observing the peculiar odour evolved by each Oil when gently heated.*

For this purpose he suggests, that a few

drops only of the oil under examination be exposed for some moments, in a small porcelain basin, to the flame of a spirit-lamp. The odour which is evolved immediately suggests that of the plant or animal from which it has been obtained: and this characteristic is valuable if observed in conjunction with the genuine oil, and furnishes accurate indications of the presence of linseed and train oils in any mixture.

2. *By the action of concentrated Sulphuric Acid on Oils.*

By mixing a small quantity of concentrated sulphuric acid with some oil, (in the proportion of about 1 or 2 parts of the former to 100 parts of oil,) very intense action immediately ensues, the temperature increases, and the mixture becomes coloured.

A plate of white glass being laid over a sheet of white paper, if we place on the former from 10 to fifteen drops of oil, and then add thereto one small drop of sulphuric acid of $66^{\circ} = 1.632$, sp. gr., a colour will soon be produced without stirring, differing according to the oil employed.

In the case of rape oil, there will gradually form at a certain distance from the drop of sulphuric acid, a greenish-blue ring; whilst towards the centre, where the action is more violent, light yellow-brown streaks may be observed.

The expressed oil of black mustard-seed likewise assumes a tinge of bluish-green; but the quantity of oil must, in this case, be increased to 25 or 30 drops.

In train oil, obtained from the whale or stock-fish, a very peculiar motion occurs, commencing at the centre and extending to the outside, whilst a red colour is observed, which grows more and more vivid, until after ten or fifteen minutes, when the margin assumes a violet tinge, which in the course of about two hours becomes uniform throughout the mixture.

Olive oil instantly assumes a pale yellow colour, which afterwards becomes yellowish-green.

In poppy oil, and that obtained from sweet almonds, the colour approaches to that of the greenfinch, and afterwards becomes of a dead yellow hue.

In linseed oil a drop of acid produces a beautiful dark brownish red web, which is gradually converted into a brownish black.

Tallow oil (called by the trade oleic acid) is rendered brown.

If, instead of allowing the sulphuric acid to act on the oil undisturbed, both fluids be stirred up with a glass rod after adding the drop of sulphuric acid, the phenomena mentioned appear in different order.

Rape oil then assumes a uniform brown colour, without a tinge of red; and if, instead of one drop of acid, five or six are added, and mixed with the oil, the whole

mass becomes of a dead brown-red colour, not very intense, remaining green only on the edges.

By doubling or tripling the expressed oil of black mustard seed, the quantity tested gives rise to similar action, with the exception that the colour is somewhat less bright.

Train oil instantly assumes, when stirred, a lively brown-red colour, which finally passes into a dark brown and violet, without a hue of green. If mixed with five or six drops of acid, the colour is much more intense, and the violet colour sooner appears.

Seal oil assumes a yellowish-grey colour. If, however, thirty drops of oil are taken instead of ten, a colour slightly approaching to green-blue also appears, so that one drop more changes it into grey. On the addition of five or six drops of acid it receives a lively orange-yellow tint.

The oils from the olive, poppy, and sweet almonds, all assume a yellow colour, more or less dingy or grey; and by the addition of more acid the action is rendered far more violent.

If linseed oil is stirred with the rod, as before mentioned, a brownish black lump forms, and, by adding five or six drops of acid, the whole forms a resinous, black, and persistent mass. It is true that all other oils likewise become plastic by the addition of greater or smaller quantity of acid; none, however, to a similar degree, and with a colour so black, as linseed oil. The oil obtained from tallow assumes a dark dirty brown colour, which does not vary in tint by the addition of more acid.

In trade it seldom occurs that a better oil is mixed with an inferior. Oil of almonds, olives, and codfish oil, will, therefore, never be used for adulterating rape oil, but probably train, or perhaps linseed oil, and sometimes poppy oil. If we are led, therefore, by the odour to infer an adulteration—for instance, by train oil, which occurs most frequently—it is only necessary to place from ten to fifteen drops of rape oil, the purity of which is undoubted, together with as much train oil, and an equal quantity of the oil whose purity is suspected, and to add to each of them a small drop of sulphuric acid. From the colour produced an inference may be drawn as to the purity of the oil, and by the difference of tinges from the vivid red of the train oil, and the bluish green of rape oil, the extent of adulteration may be ascertained. In this manner I detected adulterations made with half the quantity of an inferior oil; and the areometer bore further testimony to the precision of my observations.

In undertaking an experiment, the commencement of the reaction must be accurately observed, with the several oils placed beside each other; for the colours, after a quarter of an hour has elapsed, are

less distinct, and the mixture should, for the purpose of attaining to greater certainty in the first experiment, be left undisturbed; in a second stirred with a glass rod. It is likewise necessary to avoid employing more than one drop of the acid to ten drops of oil, since otherwise the reaction which ensues is too violent.

If the presence of linseed oil be suspected in train oil, this will be discovered, if the mass is left undisturbed, by a rather intense brownish red colour; if disturbed, by a brownish black colour. The intensity of the latter is increased by the increased addition of acid, and also the consistence of the moisture.

The adulteration by poppy oil is seldom met with in commercial rape oil, because it is commonly much dearer than the latter. In the present year, however, the reverse was the case, and rape oil was found to have been adulterated with poppy oil. In this case the colour produced is of a very slight bluish green, approaching somewhat to yellow, but sufficiently distinct to admit of an inference being drawn, as to the adulteration, with perfect certainty. In such cases the specific gravity of both oils must be received as the sole criterion for identifying them.

It has been reported that tallow oil has several times been mixed at Paris with rapeseed oil: besides the brownish colour produced by sulphuric acid, the tallowy smell, the brown colour, the acid reaction, and last, although not least, its density, which is less than any other of the fixed oils, are such decisive characteristics, that we must be blind indeed if we do not instantly discover this fraud.—*Annals of Chymistry and Practical Pharmacy.*

CASES OF POISONING

WITH CERATE MADE WITH ARSENICATED CANDLES.

By DR. ERRARD, of Jujurieux (Ain.)

CASE I.—A man, aged 53, was recovering from pneumonia, which had been successfully treated by repeated bleedings, when, on my recommendation, compresses covered with cerate were applied to the sores produced on both arms by the application of blisters.

Very early the next morning I was called to the patient, whom I found in an alarming state. His loins were painful; his tongue red, dry, and cracked; his thirst was insupportable; and he suffered from griping, not followed by stools. I observed involuntary contractions in the muscles of the lower limbs and of the back; the pulse was small, irregular, and frequent. The patient had headache.

I did not examine the sores, which were reported to be red and inflamed. The patient died in the evening.

I suspected that some injurious remedy had been administered, not being able to explain otherwise the appearances of such serious symptoms which had no connexion with the previous disease; but the relations of the deceased gave negative answers to all my questions asked with this view, and I did not push my inquiries farther.

CASE II.—A week after the termination of the previous case, a young girl, to whose thigh I had ordered a blister to be applied, to relieve a headache, arising from amenorrhœa, put a compress covered with cerate on the sore. She soon felt extreme pain, which obliged her to take off the dressing, and I was sent for. The girl complained of intolerable thirst, of nausea, and of pain in the epigastrium. Her tongue was red; the sore of the thigh was inflamed, and bled a little. There were jerking movements in the limbs.

I prescribed a soothing potion, a *tisane*, enemata, fomentations with mallow water, and a bath; and the patient was cured in a few days.

The relations considered the application of the cerate to the sore as the cause of the symptoms. I examined the remedy in order to satisfy them. It was white, unctuous to the touch, and, in short, of normal appearance. Still I immediately recollected that in the first case, the serious symptoms, which were the forerunners of death, resembled those of the girl, and had also appeared soon after the application of compresses covered with cerate to the sores of her arm. I also recollected that a short time before, a mother had complained that a cerate which she had applied to her child had increased the existing disease, which was an inflammation of the ale of the nose. On inquiry, I found first, that the cerate used in the three cases had come from the same house; and secondly, (which explained the symptoms produced) that it had been made with candle-ends at 1 fr. 60 cent. (sixteenpence) per pound; these candles being of a new kind, in the manufacture of which arsenic is used.

I regret that these cases have not been made more valuable by a chemical examination of the cerate used. Still they show, I think, the necessity of enlightening the public concerning the composition of those candles; for in almost every village there is a small *pharmacie* kept by pious ladies, or by nuns, who often make cerate with the ends of candles which have been used in the church of the place; and candles made of tallow bleached and hardened by arsenic are beginning to be employed in churches.—*Gazette Médicale*, Nov. 5, 1842.

ON THE USE OF THE NITRATE OF SILVER IN SUBSTANCE.

To the Editor of the Medical Gazette.

SIR,

IN cases of intolerance of light, with inflammation, or a granular state of the conjunctiva, ulceration or opacity of the cornea, and other affections of the eye, besides the appropriate constitutional treatment, I have been for years in the habit of lightly applying, with the greatest benefit, the nitrate of silver in substance, *externally*, to the lids, with the view of allaying the morbid susceptibility of that portion of the fifth pair of nerves supplying these parts. Even in intolerance of light, where other structures are involved, sometimes considerable benefit is experienced by this harmless and simple treatment. I am induced thus briefly and publicly to announce the fact, from reading a paper by Dr. Hocken entitled, "A New and Improved Plan," &c. &c. Now as Dr. Hocken has, with other pupils, been in the habit of seeing my practice at the out-patients' room at St. Bartholomew's Hospital, I think it only justice to myself to state, that this treatment has been there successfully employed, not only in "slight ophthalmic affections," but in many severe ailments, and although decidedly an "improved plan," it is certainly not "new" either to my pupils, or to your obedient servant,

THOMAS WORMALD.

Bedford Row, Nov. 29, 1842.

IMPROVED METHOD OF ADMINISTERING COD LIVER OIL.

DR. URE has suggested the adoption of cod livers as a diet for patients who are recommended to take the oil. In order to prevent the loss of oil during the process of cooking, he recommends the livers to be immersed entire in boiling water, to which a sufficient quantity of salt has been added to raise the boiling point to about 220° Fahr. The sudden application of this high temperature coagulates the albumen of the liver, and prevents the escape of the oil. When the liver is cut, the oil exudes, and mashed potatoe may be used as a vehicle. Dr. Ure informs us, that having been advised to take cod liver oil, he found the nauseous flavour very objectionable, until he contrived the above plan, which he finds to answer extremely well.—*Pharmaceutical Journal*.

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

BY ROBERT LEE, M.D. F.R.S.

LECTURE IX.

*On the Formation and Structure of the De-
cidua Reflexa, and the Purposes served
by the Decidual Cavity in the Human
Ovum.*

ON the 10th of March, 1832, a young woman, who was in the second month of pregnancy, poisoned herself with oxalic acid. The uterus had acquired double the size which it usually exhibits in the unimpregnated state. It was five inches long, three and a half in the greatest lateral direction, and two inches in the antero-posterior diameter. A longitudinal incision was carried down the middle of the posterior surface, crossed by a transverse one parallel to the entry of the fallopian tubes. The thickness of the parietes of the uterus, though greater than in the unimpregnated state, were not proportionate to the general increase in the dimensions of the organ: they were four lines at the fundus, and six lines at the cervix, gradually increasing towards that part: the chief difference was observable in the already enlarged size of the uterine venous sinuses. The deciduous membrane, which closely adhered to the inner surface of the uterus, was then laid open by two incisions parallel with the longitudinal and transverse incisions previously made in the parietes of the uterus. The cavity of the uterus being exposed, the ovum, about the size of a pullet's egg, came into view, and was observed to be situated towards the lower part of the uterus. It was lodged entirely in the cavity of the body

of the uterus, and no part of it extended into the cervix. The part of the cavity to which it adhered was included between two parallel lines, drawn, the one transversely across the uterus at the distance of half an inch below the entry of the fallopian tubes, the other at two inches distance from the os tincæ: consequently, the ovum was situated altogether below the entry of the fallopian tubes, and was unattached both at its upper and lower part, leaving a free space or canal between it and the os tincæ, corresponding to the shape of the elongated cervix, and a much larger cavity, which was the decidual cavity, between the upper part of the ovum and the fundus uteri. Intervening between the superior and unattached surface of the ovum and fundus uteri was a broad cavity, measuring three inches in the lateral, and one and a half in the antero-posterior diameter, and which appeared at first only a few lines in depth, but on further inspection was ascertained to be nearly two inches in depth. The upper concave surface of the cavity formed by the decidua lining the fundus uteri, or uterine decidua, was irregular, and slightly reticulated. The inferior convex surface formed by the decidua covering the villi of the chorion, or decidua reflexa, was perfectly smooth, resembling somewhat the external serous surface of the uterus. On examining this with a magnifier, numerous small elliptical openings were seen in every part of the membrane. Into this large cavity, between the decidua reflexa and the decidua vera, the fallopian tubes opened by palpable orifices; that on the left side, by which the ovum had entered the uterus, being rather more than a line in diameter; that in the right rather less. The cavity thus formed between the decidua lining the fundus uteri, and the decidua covering the upper and unattached portion of the ovum, or decidua reflexa, was filled with a red-coloured serous fluid. The ovum was next laid open by an incision through the chorion parallel with the longitudinal incision of the

uterus, and the amnion enclosing the embryo was brought into view. The placenta was situated principally over the cervix and posterior part of the uterus, and the decidua, closely adhering to the placenta, passed across the upper part of the cervix uteri in the form of a thick reticular membrane. The decidua was then observed to extend upward between the uterus and chorion, every where firmly connecting these together as high as the entrance of the fallopian tubes. From this point the deciduous membrane was spread out in two different directions—viz. over the upper convex and unattached surface of the ovum to form the decidua reflexa, and over the whole concave surface of the fundus uteri to form the uterine decidua. Between these membranes was the decidual cavity, into which the fallopian tubes freely opened.

If you examine this gravid uterus of two months, you will see the chorion and amnion enclosing the embryo, and umbilical cord, and the placenta, covered with its decidua, adhering all round to the upper part of the neck of the uterus. You will also see clearly that the decidua reflexa lies entirely above the villi of the chorion, on that side of the ovum where the placenta does not exist, and where the ovum is not attached to the uterus. In all the diagrams from Dr. Hunter, Wagner, and other anatomists, which you have seen, the placenta has invariably been represented as adhering to the fundus uteri, and the decidua reflexa has been situated near the cervix, and appearing as if mechanically depressed or pushed down before the chorion or ovum. But in this preparation it is obvious that the decidua reflexa could not have been pushed down before the ovum, because it lies above or covers the ovum—the ovum lies between the decidua reflexa and the cervix uteri—and as the ovum enlarged the decidua reflexa must have been forced upward to the fundus uteri, which was lined with the decidua vera, instead of downward to the cervix. The decidual cavity is, you observe, at the fundus uteri, above the ovum, and both fallopian tubes open into this cavity by palpable orifices. Instead of being covered with the uterine decidua, this membrane passes into them, and they are left completely pervious, so that no membrane existed which the ovum could mechanically push before it. I am not aware of the existence of any other specimen of the gravid uterus at so early a period, in which the placenta is adherent to the neck of the uterus, and the decidua reflexa is placed above the villi of the chorion, or that part of the ovum which is not attached to the uterus; but it is impossible to doubt that in all cases of placental presentation in the early months, the decidua reflexa completely invests the villi of the chorion,

and that the decidual cavity is situated at the fundus of the uterus. If the statements of the authors above alluded to, and the generally received opinions respecting the formation of the decidua reflexa, were well founded, it would follow, that in all cases the ovum would attach itself to the uterus by the placenta, either directly over the edges of the fallopian tubes, through which it had descended, or to its immediate vicinity, and that the deciduous membrane would never be found interposed between the uterus and placenta, as it invariably is. The facts which have now been adduced, and will hereafter be stated, demonstrate that the fallopian tubes are open in the early months of gestation, that the ovum may attach itself, by the placenta, to the fundus body, or cervix uteri, and that the deciduous membrane forms neither a shut sac nor inorganic layer, prior or subsequent to the arrival of the ovum in the cavity of the uterus. These circumstances are also strictly in accordance with the fact, that when the ovum can first be perceived, it lies loosely imbedded in the soft, flocculent, albuminous matter which, at this period, coats the inner surface of the uterus, and that this pulpy semifluid matter becomes gradually converted into those delicate organised membranous layers by which the attachment of the ovum to the uterus is so firmly secured, and the most important function of the ovum performed during the whole period of pregnancy. The albuminous substance interposed between the uterus and chorion becomes the decidua uteri, or decidua vera, while the albuminous matter which envelopes the unattached hemisphere of the ovum becomes the decidua reflexa. To whatever part of the uterus the ovum adheres by the placenta, its relation to the deciduous membranes will be the same, the uterine decidua forming the connecting membrane between the ovum and uterus, and the decidua reflexa covering only that part of the chorion which hangs loose within the cavity of the uterus. Dr. William Hunter offered no explanation of the manner in which the decidua reflexa is formed, and Dr. Baillie, who completed his description of the gravid uterus and its contents, says, that the manner in which the decidua envelopes the ovum has never yet been observed, and therefore can only be a subject of conjecture. The most probable supposition is, that the ovum passes from the ovarium into the cavity of the uterus, while the coagulable lymph is pouring out by the arteries of the uterus, which is afterwards changed into decidua. "One can hardly imagine," he says, "that the ovum should make its way into a membrane which is already formed, and, though tender, yet capable of some degree of resistance.

In the following figure are represented

the appearances above described in the gravid uterus of a young woman who destroyed herself by oxalic acid in the second month of pregnancy.

a, The entrance of the left fallopian tube into the decidual cavity; *b*, the uterine orifice of the right fallopian, also pervious, and opening into the decidual cavity; *c*, the decidua vera, or decidua uteri, coating the inner surface of the fundus uteri, and forming the outer wall of the decidual cavity; *d*, the decidua reflexa lying above the ovum, and covering all that portion of it which is not attached to the uterus, and which is occupied by the villi of the chorion; *e*, the decidua vera, or uterine decidua, passing down between the uterus and placenta; *f*, the chorion; *g*, the amnion; *h*, the placenta adhering to the neck of the uterus, and the placental decidua torn passing across the upper part of the cervix, which is not shortened.

M. Velpeau thinks that the membrane which lines the fundus uteri in this preparation is not the decidua vera, but the mucous membrane of the uterus altered. M. Coste several years ago, when in London, before examining this uterus, had formed the same opinion. To determine the point, it was removed from the spirit, and a much larger portion of the decidua detached from the fundus of the uterus than is seen in this drawing, and the correctness of the description which I have given was so completely demonstrated, that he expressed himself perfectly convinced that the decidua reflexa lay above the unattached part of the ovum, and that the fundus uteri was lined with the decidua vera; the lining membrane of the uterus being distinctly seen after the separation of the decidua from it. M. Coste admitted that before examining this preparation he doubted the existence of the decidua reflexa; as some other anatomists on the continent have done. But there is another subject of far greater importance than the origin and mode of formation of the decidua reflexa; viz.

the purposes served by the decidual cavity in the ovum. I believe the decidual cavity is peculiar to the human ovum, and does not exist at all in the ova of the lower animals; it certainly has no existence in the ova of any of the larger quadrupeds.

In 1832, M. Breschet stated in his work entitled "*Etudes sur L'Oeuf*," &c. that this cavity always contains a fluid, which at an early period is colourless, mucous or slightly albuminous, and which has at a later period a milky appearance, and resembles an emulsion, united to a little mucilage of a faint rose colour. He says it must amount to several ounces when the ovum has reached the cavity of the uterus, and at the time the decidua reflexa begins to be formed; but he admits he was never able to collect the fluid so as to have it submitted to chemical analysis. This fluid he called *hydropericione*, having previously applied, without the slightest advantage, the term *fœtal perione* to the decidua reflexa, and uterine perione to the uterine decidua. M. Velpeau, in his work on *Embryology* (1833), likewise stated that

the decidual cavity contains a fluid which he has thus described. "*Le liquide qui remplit sa cavité et tient ses deux lames écartées, parfois tout à fait limpide, est le plus ordinairement rougeâtre, filant, semblable à du verre fondu, ou mieux, à du blanc d'œuf. Je n'ai point pensé à le faire analyser.*" M. Breschet thinks that this fluid promotes the slow and regular dilatation of the uterus, and protects the ovum; and that it contributes to the nutrition of the ovum and embryo, before the vessels of the embryo and the vesicula umbilicalis are formed. It is difficult to believe that the decidual cavity, if it exists at all at this early period, should be able to contain several ounces of hydroperrine.

The following facts seem to prove that the circulation of the maternal blood in the human ovum during the early months is entirely carried on by the decidual cavity and its walls, and by the cells of the placenta and chorion. In a healthy recent ovum of six or eight weeks, numerous small tortuous canals or arteries are visible in the placental decidua. These vessels usually project a little beyond the surface of the placental decidua, and the orifices with which they had anastomosed with the arteries of the uterus are very distinct. These decidual arteries are often seen in the placental decidua filled with blood, at the end of the ninth month, and have been minutely described by Dr. W. Hunter. It is now admitted by all anatomists that these curling arteries or canals in the placental decidua in the latter months, convey the maternal blood from the uterine arteries into the interstices or cells of the placenta, and that there is no other channel by which the blood can be conveyed into the placenta. Elliptical openings can also be seen in the placental decidua both in the early and advanced months, which anastomosed with the oblique venous apertures which are always found in the lining membrane of the uterus where the placenta has adhered. A communication is formed by these openings between the cells of the placenta and veins of the uterus, and the blood which has been carried by the decidual arteries into these cells flows back into the uterine veins, through these oblique openings in the placental decidua. At the end of the second month of pregnancy only about a fourth part of the chorion is occupied by the placenta, the remainder being covered with the villi of the chorion and decidua reflexa, and is unattached to the uterus. It is obvious therefore that at this time the whole of the blood which enters the ovum, and which is invariably found distending the cells of the placenta and chorion, must pass through the arteries of the placental decidua. But the blood which flows from the cells of the placenta into the cells of the chorion

cannot flow back and pass through the openings in the placental decidua into the veins of the uterus, unless there exist two currents of blood in the cells of the chorion flowing in opposite directions, which it is impossible to admit. The blood, therefore, which fills the cells of the chorion, must pass by another route into the venous system of the uterus than by the elliptical openings in the placental decidua; and it can only be through the decidua reflexa and decidual cavity, which I now believe performs the office of a great venous sinus.

If you examine the decidua reflexa in a perfectly healthy ovum, you will observe numerous small oblique openings, with smooth edges, in the whole of the membrane, but in greatest number near the margin of the placenta, where an angle is formed by the uterine decidua reflexa. These openings in the decidua reflexa communicate with the cells of the chorion, and the cells of the chorion with those of the placenta. I have repeatedly filled all the cells of the chorion and placenta with air, by introducing a blow-pipe into one of these apertures in the decidua reflexa; and when the air has filled all these cells, it has escaped freely through the surrounding openings in the decidua reflexa. The same has been done with mercury; and in this ovum [exhibiting it] the whole of the cells of the chorion and placenta have been filled with injection introduced by one of these openings in the decidua reflexa. When the cells were filled with injection, it began to escape from the openings in the decidua reflexa around, and you can see the injection hanging through some of the openings. These facts prove that there exists, by means of these openings in the decidua reflexa, a free communication between the cells of the chorion and the decidual cavity. But there is another still more conclusive proof. If you take a recent ovum, the decidua reflexa of which is in a healthy condition, and make slight pressure, you will see the maternal blood begin to flow through these openings from the cells of the chorion; and I can now shew you several ova, in which coagula of the fibrine of the blood are seen filling these openings, and were hanging through them into the decidual cavity. These coagula could not have been formed in these canals if the blood had not been actually flowing through them, before the separation of the ovum from the uterus. The decidua reflexa, besides, is covered, as you see in this preparation, by a fine membrane like epithelium, which has been dissected off, and floats in the spirit, and of which a beautiful drawing has been made by Mr. Perry. This fine membrane not only covers the whole decidua reflexa, and passes into the openings in it, but it is also reflected over the whole inner surface of

the uterine decidua. The whole decidual cavity is therefore lined with this very fine membrane, which resembles the serous membrane of cavities which contain blood.

In many morbid ova expelled in abortion the decidua reflexa is in a hard, altered state, and few or no openings like those now described, can be observed in it, or only close to the margin of the placenta. The cells of the

placenta and chorion are generally observed in these ova to be full of masses of coagulated blood,—a condition which is usually called apoplexy of the ovum, and appears to arise from the obliteration of the canals in the decidua reflexa.

The appearances presented by the orifices of the canals in the decidua reflexa are seen in the following drawings.

A, the decidua reflexa, with a few of the smooth orifices of the canals passing between the cells of the chorion and decidual cavity—natural size. The openings had almost entirely closed in that part of the decidua reflexa, which was most remote from the placenta, and the villi of the chorion had here also nearly disappeared.

B, the openings in the decidua reflexa as seen through a simple lens of an inch focus.

C, the inner surface of a small portion of the uterine decidua or decidua vera, unusually thick and rugous.

D, a magnified view of the same membrane, with a few small orifices of vessels.

In these figures are represented the openings in the decidua reflexa and uterine decidua, as seen in another ovum of an earlier age.

A, a small portion of decidua reflexa magnified.

B, inner surface of uterine decidua, with the veins passing obliquely through the membrane to the uterine surface.

The outer wall of the decidual cavity is formed by the uterine decidua, which varies much in thickness. The outer surface of this portion of the decidua, which had adhered to the uterine wall, is usually very

irregular, and long slender filaments from thick roots are often seen projecting from it: some of these filaments appear to be hollow. A great number of openings are also visible on the outer surface of the uterine decidua, which are the terminations of venous canals which pass obliquely through this membrane from the smooth inner surface. I have not observed any considerable arteries in this portion of the decidua, similar to those which are seen in the placental decidua. The inner surface of the uterine decidua is comparatively smooth, and, seen through a magnifier, appears not very unlike the convolutions of the brain: at the bottom of these are deep grooves or depressions, in

which are situated numerous minute apertures of a circular or oval form. There are some of these openings on the raised portions of the membrane as well as in the grooves. Into these openings the epithelium which lines the decidual cavity passes, and coats the venous canals in the decidua uteri. These veins pass obliquely through the membrane: they frequently communicate together so as to form a great plexus, and gradually increase in size as they approach the uterine surface. The appearances presented by the orifices of the veins on the inner surface of the uterine decidua are seen in these figures, but by no means so clearly as in the preparation and drawing.

A. The orifices of the veins of the uterine decidua opening into the decidual cavity: natural size.

B. A portion of the same membrane as seen through a good lens.

I once saw the decidua uteri adhering through its whole extent to the inner surface of the uterus in the second month, with all these veins distended with firm dark clots of blood. On separating the membrane gradually, these coagula were seen passing from the decidual veins into the veins of the uterus. The trunks of the veins were on the uterine side of the membrane, and they had evidently been conveying blood from the decidual cavity to the veins of the uterus.

All the veins of the uterine decidua, in several of these preparations which you have seen, are filled with coagula of the fibrine of the blood; and by following these, the course of the veins from the inner to the outer surface of the membrane can be traced. In *this* preparation all these veins have been filled with a white injection; so that the direction of the vessels, and their connection with one another, and their termination on the outer surface of the membrane, can be clearly seen. It was by observing the manner in which the coagula of the fibrine of the blood passed through the placental decidua into the veins of the uterus, and by following coagula from fibrous tumors of the uterus into their veins, that I first became acquainted with the manner in which the circulation of the blood is carried on in the placenta, and in fibrous tumors of the uterus. It was likewise by tracing the coagula which occasionally distend the veins of the decidua uteri, that I was first led to suspect that

these vessels do not convey blood or fluid of any kind from the uterus into the decidual cavity, as many physiologists maintain, but remove from this cavity that blood which had passed into it, through the openings in the decidua reflexa, from the cells of the chorion. In several specimens of ova expelled in abortion, with the decidual membranes entire, I have seen the cavity filled with fluid and coagulated blood. Coagula of the fibrine were seen hanging out of the orifices of the canals in the decidua reflexa in this specimen, of which a drawing has been made. The blood could not have been forced here into the decidual cavity by any accident, as Breschet states was the case with the ovum described by Heusinger, where the decidual cavity was likewise full of blood.

From these facts, it appears probable that,

in the early months, the maternal blood is conveyed by the arteries of the placental decidua into the cells of the placenta and chorion, and that the blood which is not returned directly back to the veins of the uterus, through the venous openings in the placental decidua, flows from the cells of the chorion, through the decidua reflexa, into the decidual cavity; and from thence into the veins of the uterus, through the venous canals of the uterine decidua. As pregnancy advances the villi of the chorion and decidual cavity gradually diminish; and before the fifth month they have almost entirely disappeared; and the circulation of the blood is effected solely by the placenta, which has rapidly enlarged. The canals in the decidua also disappear, and the membrane is very thin, and presents a complete cribriform or lace-like appearance.

Diagram, from Wagner, of the gravid uterus at the end of the fourth month, laid open, and the involucra of the ovum delineated in situ. In the cervix there is a great plug of gelatinous matter.

a, os externum; *b b*, gelatinous plug filling the cervix uteri; *c c c*, the uterus reflected in four flaps; *d d*, decidua vera lining the uterus; *f f*, the decidua reflexa passing into the vera by a circular fold, slit smooth, and unconnected inferiorly; at *f l f l*, however, it is rough, as at this part it was in contact with the decidua vera, and was only separated from this by force; *g*, villi of the chorion; *h*, amnion; *x x x*, supposed tunica media, lying between the amnion *h*, and the chorion *f*.

LECTURES
ON THE
PRINCIPLES AND CLASSIFICATION
OF DISEASE,

Delivered at St. Thomas's Hospital,

By THOMAS HODGKIN, M.D.

Lecturer on the Theory and Practice of Medicine
at St. Thomas's Hospital School.

GENTLEMEN,—A field of such wide extent as the study of medicine, requires, for its successful cultivation, that numerous divisions should be employed. These, like the limits of physical geography, may be inherent in the nature of the subject; or, like those of political geography, they may be conventional or arbitrary. Divisions of these two characters may be multiplied almost indefinitely, and different principles may be assumed as the rule for their adoption. I regard it as unnecessary now to enter into the principles of arrangement, but shall proceed to adopt such divisions of the subject as its nature seems to indicate, and usage has sanctioned, until we arrive at points at which the consideration of classification may be regarded as important.

The object of our art being to apply remedies or means of relief to the various diseases with which the human frame may be afflicted, it is obvious that our first care must be to become acquainted with the characteristics of diseases. For this purpose, it is essential that they be accurately and intelligibly described. To produce these descriptions with sufficient minuteness and accuracy requires that the powers of observation should be especially cultivated for the purpose, and, that to avoid incessant and tiresome repetitions, and to ensure a greater degree of precision, the use of numerous terms should be introduced. The proper description of disease constitutes the division to which the term nosography has been given. It is of the greatest importance that the student of medicine should possess clear and accurate nosological ideas. Had attention more generally been paid to this, many perplexing discrepancies in medical authors would have been avoided, and those who have no intention of becoming authors, but merely design to study and practise their profession, will find the advantage of this accuracy when engaged in the treatment of disease, and in the conferences and correspondence to which it must give rise.

Nosography, or the description of disease itself, admits of division. The phenomena which the patient presents to our observation, whether in the colour, the temperature, the moisture or dryness of his skin, the appearance of parts accessible to examination,

the character of his various secretions, the pains of which he may complain, the perceptions which he has lost, and the changes in those which he retains, constitute what are termed *symptoms*; and the description of them constitutes that division of nosography which is termed *semiography*; as the laws of their production, and the conclusions which they furnish for the distinction of diseases, is termed *semiology*.

But when we have found the patient labouring under an assemblage of symptoms, the question naturally arises, what induced them? Have they been brought on by what he has eaten, or done, or omitted to do? Has he been subjected to any remarkable influences either of temperature or moisture in the atmosphere? Has he been in any situation known to produce similar symptoms in other persons, or been in communication with disease? Here we have the reason for another division of nosography, to which the name of *atiology*, or the knowledge of the causation of disease, is given. When nosography has supplied a full descriptions of disease characterised by their symptoms and causes, they would, without some system of arrangement, exhibit almost endless multiplicity, and consequently the greatest perplexity. Something, therefore, is required to be done with reference to the diseases with which nosography has made us acquainted, analogous to that which natural historians, whether botanists, zoologists, or mineralogists, have done for the countless objects of their studies. The perfect parallel between all these cases is exhibited in the fact, that Linnæus, the great author of the best artificial classification of plants, and of a similar classification of animals, being himself a physician, formed a classification of diseases also. The division of medical science which comprehends the classification of diseases has been called *nosology*. The importance of this subject, the great variety which it admits, and the difficulty of establishing a perfectly satisfactory system, are exhibited in the number of authors who have treated on the subject, and offered classifications of their own to their professional brethren. We have not only the classification of Linnæus, to which I have just alluded, but that of his predecessor, Sauvages, who must perhaps be regarded as the father of nosology; that of Cullen, which, notwithstanding various imperfections, has many merits, in addition to its general adoption in this country, to recommend it to every English student; that of Dr. Young, who never turned his attention to any subject without bringing to bear upon it profound learning, patient and careful observation, and remarkable original views; that of Mason Good, and a variety of others, on which it is unnecessary for me

here to dwell. In a subject so extensive as that of nosology, numerous authors have appeared, who, without attempting to grapple with the whole range of diseases, have taken up particular sections of the subject, into which they have introduced subordinate classifications, some of which are of great importance, and merit particular study. Of this description is the classification of diseases of the skin by Dr. Willan, also several classifications of the eye by distinguished oculists; and when I tell you that nosographers of the eye have extended the list of diseases affecting that organ to the extraordinary number of two hundred or more, you will readily believe that classifications would be necessary to relieve the memory, were there no other organs, with their respective catalogues of diseases, requiring a proportionate share of attention.

Various diseases possess certain characters in common, which may lead to their being occasionally spoken of in association, without its being designed to bring them together in nosological classification: thus, some diseases are capable of being communicated from person to person, whilst others are not so. Hence arises the very important distinction of infectious and non-infectious disorders. Those which agree in this respect may have no other title to be considered in the same family. The limits between the infectious and non-infectious diseases are by no means distinctly drawn, and the highest authorities have been at variance with each other on this very important practical question.

The distinction of diseases into the acute and the chronic is of the same description. Diseases properly placed at a wide distance from each other in nosological arrangement, may nevertheless agree in the possession of one or other of these characters; and diseases properly brought together in scientific arrangement may differ in these respects. Even the same disease may be seen in some individuals in an acute, and in others in a chronic form. It is equally certain that the precise limit between the acute and the chronic is not defined, and although conventionally the terms are as well understood as perhaps any which medical men are in the habit of employing, I do not remember to have heard it even suggested that within the duration of a certain number of days a disease should be regarded as acute, whilst if it extend through a greater number it is to be reckoned as chronic.

We commonly esteem a disease acute if the stages which mark its commencement, acme, and termination, are comprehended within a period of two or three weeks; but if, contrary to what is usually observed to take place in cases of the same disease, it should happen to be prolonged at a particular stage, it would be said to assume a

chronic character. Common catarrh affecting the mucous membrane of the respiratory organs exhibits perfect examples of these two characters. Cancer of the female breast, a disease which, if not timely removed by operation, proceeds to a necessarily fatal termination, passes so slowly through the stages of its progress that it may be protracted for many years; and if, in a particular individual, in consequence of some constitutional peculiarity, cancer of the breast were to pass into the ulcerative stage, spread in a few weeks to the neighbouring parts, and carry off the patient in six months, it might be said to have assumed an acute character. Hence you will perceive that the terms acute and chronic possess a comparative force, and that it is only by acquaintance with the diseases to which they are applied that we can comprehend the sense in which the speaker or writer may employ them.

Diseases are said to be endemic when, like goitre, or the enlargement of the thyroid gland—like elephantiasis, a peculiar disease of the cutis and subjacent cellular membrane—and like the plague—they occur in particular districts or regions; yet cases of disease, which for the most part are so limited, may occasionally be met with in other situations. Again, a disease may, at a particular time, be found to affect a remarkable number of individuals in the same locality, indicating the temporary prevalence of some pernicious influence; yet, of these very diseases, rare or even solitary examples may at times be seen in the same or other localities; when, in contradistinction to the term epidemic, they receive the appellation of sporadic. A disease may at the same time be both epidemic and endemic, of which the most striking example is perhaps that of plague, which, whilst in our own times it is so strictly endemic that it rarely occurs beyond the territories bordering on the Levant, is also so strictly epidemic that, even in the situations which it is known to affect, its occurrence, except at particular seasons, would be regarded as an extraordinary circumstance. Though the causes which operate in the production of endemic and epidemic disease are involved in great obscurity, they well merit continued careful research; and, with respect to the epidemic at least, the careful attention which has been devoted to the subject during a period of many years has led to the discovery of certain data which are of the highest importance both in the treatment of disease and in the employment of measures for the preservation of individual and public health. The field of research in this direction invites the perseverance of sagacious inquirers, who can scarcely fail to be rewarded by the discovery of important truths.

Diseases are said to be local or constitu-

tional. Thus, bronchocele, ovarian dropsy, and hydrocele, may be regarded as strictly local affections; no other organs of the body, and no functions of the system, being deranged by their existence, except those which are in immediate relation to the parts in which they exist. It can only be by their mechanical influence, by which they may eventually induce other disease, that constitutional affection can be referred to them. On the other hand, scorbutus, gout, and small-pox, may be pointed out as diseases in which the entire constitution is essentially concerned, notwithstanding the special appearance of derangement in some particular part of the body.

Some morbid affections are regarded as transmissible from generation to generation, and are consequently designated by the term hereditary diseases; although, with regard to some of these affections, the child may not come into the world labouring under the malady, as is the case with syphilis; but rather, possessing in its constitution a strong tendency to the development of the particular disease at a future period of its existence. Very careful investigators have not agreed amongst themselves on this point; some having been led by their observations to conclude that some of these diseases existed in a latent state during foetal life, whilst others have contended that they were not called into being until a subsequent period; *e. g.* the opinion entertained by Langstaff as to tubercle and malignant diseases.

Whilst I have been noticing some of the divisions of disease, I have passed over the definition of disease.

Disease has been defined as *any variation from the most perfect and healthy state of the several organs and functions of the living body*; but as few, if any, persons can be said to enjoy this universal integrity of parts and functions, who, nevertheless, are not considered to be in a state of disease, we must, as a practical distinction, adopt some other definition of the term, and the following, which has already been employed, will answer our purpose on the present occasion—namely, an uneasiness, excess, or defect, in one or more of the functions of the body or mind, recurring so often, or continuing so long, as to demand medical assistance.

Although I shall have to take up the diseases to which this description will apply *seriatim*, in connection with the parts of the body which they respectively affect, I have, on careful reflection, considered that I should be more likely to render myself intelligible to you if I commenced by offering some remarks upon disease in general, although the full elucidation of this subject belongs rather to a division of the study of medicine, which has been called general pathology, or institutes of medicine, than to that of the

practice of physic, with which, however, so far as I shall treat it, it appears to be inseparably connected.

Let us suppose a particular part of the body to have lost those conditions the possession of which constitutes the healthy state. The tokens of this change having taken place, or, in other words, the symptoms of the disease, may, as I have before remarked when explaining the term semiology, be very various; not merely depending upon the differences in the mode of local change which may take place, but in accordance with the relation which the part affected bears to the whole body. Thus, it may be so situated as necessarily to influence some very important function—it may directly interfere with respiration, with the circulation of the blood, or with the taking and digestion of food. We shall, in such cases, have symptoms depending upon the diseased state superadded to those which are the direct consequence of the disease in the part itself. We shall, therefore, simplify our view if, in the first place, we consider the derangement as taking place in a part not so essential to life as it must be when connected with the performance of the functions just mentioned. Let us go, for example, to the hand or the foot: we shall here have the advantage of considering a state of disease which does not, from its situation, necessarily produce the disturbance of any function essential to life. We have also the advantage of studying the symptoms by a more complete application of our senses, than is the case with the disease of an internal organ. You will be disposed to say this is a surgical, and not a medical case. I have purposely selected such a case, in order to exhibit the inseparable relations of these two departments, and to urge the importance of looking at surgical cases with medical eyes. It has most truly been said, *Chirurgia jauna medicina*. But to proceed. The hand, or even a part of the hand, receives some external injury, and comes into a state of disease. An uneasy sensation in the parts warns the individual that this has taken place; but if this be inconsiderable, he may experience no other inconvenience than the more or less complete deprivation of the use of his hand. If the mischief have been slight, and the part be merely protected, it soon recovers its former ease and usefulness. We have here a very simple case; yet even this affords some subject of reflection. For the part to be injured at all, implies that there must have been a derangement of structure; for pain, to have been felt, would lead us to inquire how this is produced, and for the part spontaneously to have recovered implies that a process had taken place the nature of which, though an every-day occurrence, is really wonderful, and requires investigation,

that we may, if possible, account for its not taking place in other instances, and promote its doing so. Let us look to the derangement produced. This may have been the separation of parts by some sharp instrument, in which case the wound is sufficiently obvious. A blow may have been inflicted, and, without any breach of surface having been produced, the part is rendered swollen, tense, and discoloured. Again, the part may have come in contact with hot water, which has caused it to become painful; first red; then the skin has been raised by a fluid poured out beneath it. We have, in these three cases, three different forms of injury. What is it that occasions pain in each of them? It may be simply said, oh! the nerves of the part have been irritated by the unusual state of things. But we must go a little further. In the case of the cut, it is manifest that the nerves may have been exposed; that first a solid body, and subsequently the air, has come in contact with them, and the knife being withdrawn, and the air excluded, the pain, which was sharp at first, may almost wholly cease. But in the case of the bruise there is no exposure of nerve; the parts naturally in contact with them have remained so, but they have been pressed upon with unusual force, and the pain which was felt on the infliction of the blow does not so quickly cease with the removal of the injuring cause as in the case of the cut. The swelling which has been produced shews that something has been poured out interstitially; that is to say, into the texture of the part, which becomes a cause of continued pressure, and consequent pain, provided the tension be considerable.

In the case of the scald, the nerves of the part have neither had anything brought in contact with them, nor have they suffered compression to induce pain. We have merely the influence of a higher degree of temperature, than the nerves, and the parts in which they are situated, are accustomed or prepared to endure. The sensation of severe pain is the immediate effect, and the continuance of the pain to a greater degree than may have been the case in either of the former instances, shows that something is going on in the part of a different character to that which may have taken place in them; nevertheless, the pain after a while ceases to be felt, the fluid by which the skin was raised disappears, and, as before observed, the part resumes its original condition. What has been the nature of the repair in these cases? In the case of the cut the divided parts have become firmly reunited. In the place of a mere fluid upon the cut surfaces, a solid bond of union, however small, has been produced, furnishing an example of what is called union by adhesion, or union by first intention. It is sometimes said that

this is the result of adhesive inflammation. Dr. Billing has objected to the use of the term inflammation as applied to the repairing process, inflammation being a state of disease which has ceased when the process of repair is going on. In most cases it is difficult to draw the boundary line, and the term healthy inflammation, as applied to that which is the prelude to the process of repair, will perhaps continue to be conventionally employed; nevertheless, I think Dr. Billing's criticism is just, and in some of the instances of disease which will hereafter come before us, practical suggestions may be derived from it. In the very simple and speedily terminated instance, which I have adduced, we seem to have the repairing process without the recurrence of previous inflammation. In the next case, or that of the bruise, the swelling subsides, absorption rather than deposition having characterised the process of repair; the blood which had escaped from injured vessels has either been taken up, or if it had been situated near the surface, it has perhaps come away with exfoliated skin. In the case of the burn or scald, the continuance of pain, and the progressive alteration in the appearance of the part after the heat has ceased to be applied, are, as I already remarked, the proofs that a disturbed process, or derangement of the functions of the part, has been set up, and continued. Such may have been the case in the other instances, but less necessarily and manifestly so. The pain experienced whilst this disturbed process is going on resembles that occasioned in the first instance by the application of heat. It is allayed by the application of cold, but recurs if the cold application is suspended, and with the pain the actual temperature is felt to be higher than that of the other hand in other respects similarly circumstanced. Hence the part is said to be inflamed, and the process which is set up is called inflammation; terms obviously derived from the sensible increase of temperature. The occurrence of this process not only as the result of injury, but set up by various causes at times so obscure that the part is said to be spontaneously inflamed, is so frequent and remarkable a part of the morbid conditions which we meet with, that it has very naturally been one of the most interesting inquiries into which the investigators of disease have entered, to ascertain in what inflammation essentially consists. It will be our duty to go into this distinct question at a future time. At the present moment we have rather to consider the effect of inflammation in the example adduced. If the continued pain attending the inflammation be very severe, more especially if the whole or a large portion of the hand have been scalded, the inconvenience is not limited

to the part affected: sleep is absent or disturbed; the surface of the body becomes generally hot, the pulse becomes quicker and stronger; the countenance bespeaks the uneasiness of the system; the appetite for solid food may be diminished or suspended, whilst that for fluids is, on the contrary, increased. It is now said that the accident has produced fever. The daily occurrence of instances resembling this in kind has produced a general idea of what is meant by the production of this state of fever, as well as by the term inflammation; yet the nature of this fever is really obscure, is attended with many complicating circumstances, and has exercised the patience of careful inquirers, and the ingenuity of speculators and theorists, as much or more than any other subject connected with medicine. The consideration of this question, like that of inflammation, we must reserve for another time. It is necessary, however, to our present purpose, to allude to some points connected with the subject. How is the general disturbance or fever excited in consequence of the local injury? The distressing and continued perception of pain is the fact which first excites our notice; and as we know that this is conveyed to the common sensorium through the medium of the nerves, we may attribute the production of general disturbance or fever to an influence propagated by the same channel. But we have another line of communication, which comes in competition with that of the nerves, namely that of the blood-vessels. We see that the part is reddened; we feel the increased warmth, which we know, in general terms, to be produced by the circulation of the blood; and we know, from the complaints of the patient, and, it may be, from our own touch applied to the arteries of the part, that increasingly strong pulsations are to be felt. Seeing that we have these two modes of communication, we shall perhaps do right to attribute to each a share of the effects produced; but it will hardly be right to do so without considering what may be done by each separately. It is possible for pain to be produced, of great severity and duration, without such injury in the part as materially to disturb the circulation in it; nevertheless, the whole system will seem to suffer in connection with it. Sleep may be banished, and a sense of severe distress produced. I may state, as an example, an instance which once occurred to myself. The fracture of my leg had rendered necessary the application of splints; and it happened that several days after the accident, and when the constitutional disturbance arising from it had very much subsided, one of the splints, without the knowledge of my excellent friend and skilful attendant, John Morgan, became to a very trifling degree

displaced, by which the margin of the opening left for the malleolus was brought in contact with one side of that projection. The pressure was of course not great, but it happened to be upon a sensitive part, and it was constant; and the circumstance of its having no remission seemed to render it increasingly intense. The whole system sympathised with it, and continued to do so with increasing severity for several hours, from my not at first perceiving the cause, and the mode by which it might be removed. When this was effected the relief was almost instantaneous, there being in fact no local injury worth notice: yet I am very sure that the continuance of such a cause would be sufficient to produce the most violent delirium. In severe cases of *tic douloureux* we also see what the propagation of pain through the medium of the nerves may produce, without the concurrence of much, if any, sensible local disturbance. On the other hand, we see that parts which can transmit little or no sensation of pain to the sensorium, from which they are cut off by paralysis, may become inflamed with less accompanying constitutional disturbance than is set up when such paralysis does not exist.

It is not equally easy to point out cases in which the constitutional effect is produced upon the system through the medium of the vessels, seeing that, in almost every case, the cooperation of the nerves may be contended for. A question is therefore involved, which has long been under dispute, and has been made the subject of curious and valuable researches. Nevertheless, I think I may state that the preponderance of argument is decidedly in favour of the opinion that the influence of poisoned wounds is communicated through the medium of the vascular system, and chiefly through the fluids which are conveyed, though the coats of the vessels themselves may perform some part; and in this way the cooperation of the nervous system is again contended for. There can be no doubt that some local inflammations, by which the system is greatly disturbed, whether induced by poison or not, extend along the course of the absorbent vessels, as we may see in the case of a dissection-wound, or a common whitlow. It is equally certain that inflammation may extend along the veins from the branches to the trunks; and in witnessing some of the investigations of Professor Alison, of Edinburgh, I have seen sufficient proof that local inflammation may extend along the arteries in opposition to the course of the blood. Besides these three demonstrable proofs that the vascular system may be involved in the communication which takes place between the part affected and the system generally, we may easily assure our-

selves of the increased heat extending along the limb from the inflamed parts, and of the more sensible pulsation in the arteries proceeding to it—effects which are promptly produced, and apparently in intimate connection with the production of constitutional effect.

ANSWER TO SOME CRITICISMS OF DR. LEE
ON

THE CHARACTERS OF EARLY CORPORA LUTEA.

By ROBERT PATERSON, M.D.

President of the Edinburgh Anatomical Society,
Physician to the Leith Dispensary and
Casualty Hospital.

To the Editor of the Medical Gazette.

SIR,

My attention has just been drawn to a lecture of Dr. Lee's, contained in your journal of the 11th current. In that lecture, Dr. Lee has made several statements regarding some observations on the corpus luteum, which I some time ago published in a series of papers in the 142d, 145th, and 147th numbers of the Edinburgh Medical and Surgical Journal. I deem it a duty both to myself and to the profession to correct some of these statements of Dr. Lee, in order to prevent the facts which I have recorded from being deliberately perverted.

The first of my papers on the subject in question refers to the history and characters of the early corpus luteum, and it is chiefly to it that Dr. Lee's remarks refer. Dr. Lee doubts whether three of these bodies that I have described and figured in the ovary as true early corpora lutea, are so; and observes, as to one of the cases, that it is "certain that she had never been pregnant, and that a true corpus luteum could not be found in the ovarium," because, says Dr. Lee, quoting the words of my report "the woman had been eight years married, and had had no family." Dr. Lee does not think proper to add the other circumstance, which I have especially mentioned, that there was every reason to believe that this woman, immediately previous to her death, which was ascribed to mal-treatment by her husband, had proved faithless to him, and been cohabiting with another man. Every one who knows ought of the history of impregnation will at once see the important bearing of this cir-

cumstance upon the point in question; and I deem it altogether unnecessary to add one word of comment upon the suppression of this latter fact by Dr. Lee, in his arguments upon the case.

The grounds, however, of Dr. Lee's disbelief, appear, as far as I can make them out, to be—1st, that there was no ovum found in the cases in question; 2d, the circumstantial evidence of impregnation was wanting; and 3d, the bodies have not the characters of true corpora lutea. Cases first and second, says Dr. Lee, "have not one of the characters of the true corpus luteum."

Now the true corpus luteum, as laid down by Dr. Lee himself, is a body of an oblong form, rather more than half an inch in length, and less than a quarter of an inch in thickness, having a different appearance from the stroma of the ovary, and consisting of a yellow substance enclosing a membranous lining, from which processes are sent out into the yellow substance to a considerable depth, and in some parts going quite through it, to the stroma of the ovary. In the two cases which I have recorded, and which Dr. Lee avers have not one of the characters of a true corpus luteum, they have actually all the characters which we have quoted above from Dr. Lee's description, with the exception of one, and that is the colour.

Dr. Lee seems totally unacquainted with the change of colour which the true corpus luteum undergoes from its very early to its mature state; such a change of colour, however, can be readily traced in the lower animals, as well as in early corpora lutea of the human subject. Dr. Lee, indeed, objects altogether to any analogy being deduced from observations on the corpus luteum of the lower animals; and although, in the early part of the same lecture, he mentions a host of facts drawn from experiments on the lower animals, and makes deductions from them, he will not hear of it being referred to as to any anatomical point; but, in my opinion, the inference is indisputably just, as the same process must take place in both, the anatomy of the Graafian vesicle being the same in both; and it has been used as such from De Graaf down to Dr. Lee.

It is but proper to add, that Dr. Lee considers the bodies, which I have described as not true corpora lutea in

one other particular, and in maintaining which he is peculiar. Dr. Lee avers that every true corpus luteum contains within it the two membranes of the Graafian vesicle, from the circumstance of his being able to divide the lining membrane of the cavity of the corpus luteum into two layers; but every one who is conversant with the late history of obstetric anatomy in this country, must know, that when it is required to support any particular hypothesis, it is possible to divide single membranes into layers, to deny the existence of vessels in parts where every one else sees them, and to find nerves where nobody else can find them. In several preparations of human corpora lutea which are in my possession, I could demonstrate to Dr. Lee, that the thick layer of lymph, which is enclosed within some early corpora lutea, could be torn into numerous layers, instead of the two which Dr. Lee mentions, and also that besides there is an external membranous covering to the substance of the corpus luteum.

Those bodies, then, which Dr. Lee states have not one of the characters of true corpora lutea, strange as it may appear, answer precisely to his own description of those parts.

But to return to his objections. *First*, there was no ovum found in the cases in question; and *second*, the circumstantial evidence of impregnation was wanting.

"The proof of conception having taken place," says Dr. Lee, "was wanting." "A membrane like the decidua has been met with when there was no pregnancy, or has been expelled in dysmenorrhœa."

Although there was no ovum found in the cases in question, we cannot admit Dr. Lee's inference that the circumstantial evidence of impregnation was wanting. The ovary was enlarged, and contained a body answering the description of the true corpus luteum, as given by Dr. Lee himself. The uterus was enlarged, and contained a soft decidual membrane. It was unnecessary, in my observations on the corpus luteum alone, to state the grounds for believing the membranes found within the uterus to be truly decidual. I now, however, beg to state, that these decidual membranes were examined by Dr. Sharpey, of London, when com-

pleting his observations on the tubular structure of the true decidua, and were considered by him, as well as by Drs. John Reid, Simpson, and Thomson, as possessing all the characterizing marks of true decidua; and, indeed, it was the decidual membrane of my 4th figure that Dr. Sharpey chose to delineate in his note to Müller's Physiology (translation), as exhibiting the structure of this membrane very distinctly marked.

With a true corpus luteum, then, in the ovary—a true decidual membrane in the uterus—is Dr. Lee entitled to say that here conception had not occurred? I speak not of impregnation, but conception.

Dr. Lee, from the reasoning he has adduced in the early part of the same lecture, drawn from the lower animals as well as the human being, knows that the ovum is a certain length of time in reaching the uterus; and Dr. Lee must be perfectly aware that cases from time to time occur affording an opportunity of inspecting these parts between the period of conception and that at which the ovum reaches the uterus. I am happy, however, to adduce a case in point, which was detailed by Dr. Allen Thomson, in his lectures on embryology, last summer.

Dr. Allen Thomson's name, in points connected with embryology, is universally allowed to be unquestionable; and he exhibited a recent case where the date of conception was precisely known, and where death took place exactly three weeks after that event; and yet, although there was a corpus luteum in the ovary (very similar in appearance to my 2d fig.), which he considered as a true one, and a decidual membrane in the uterus, which bore all the characters of the true membrane, yet no ovum was found in the uterus.

But, indeed, I cannot but feel honoured at having my opinions on the subject of the corpus luteum questioned by Dr. Lee in the same page in which he questions the accuracy of the opinions of Professor Baer, of Königsberg, the first embryologist of the present day. Dr. Lee obviously treats his opinions with as little respect as he has done mine, for he says that Professor Baer has promulgated erroneous views respecting the true corpus luteum; in fact, that he mistook a false

for a true corpus luteum: statements which are looked upon as strong when used on ordinary occasions, but certainly especially strong when used to denounce the opinions of one of the most accurate physiologists of modern times.

But seeing, Mr. Editor, that Dr. Lee cannot recognise the true corpus luteum in its earlier stages, when delineated by Baer, or when carefully figured by myself from recent preparations, may we not as justly question whether Dr. Lee himself actually knows a true corpus luteum? And certainly, if no ovarian body is a true corpus luteum but that which is lined by a double membrane, it will, I fear, be difficult for any one to present him with a genuine specimen, unless they have previously taken the trouble to cut the single contained lymphic membrane into two layers, and into two layers only.

These remarks have already extended much further than I expected; I shall therefore allow the subjoined letter of Professor John Reid, of St. Andrew's (who has devoted much attention to the subject, and on whose masterly powers of observation on anatomical points the medical profession of Great Britain has justly placed so much confidence), to confirm what has been said, and to answer some of the remaining criticisms of Dr. Lee.

Trusting that Dr. Lee will at some future period, on a full reconsideration of the subject, see reason to change his anatomical opinions on the corpus luteum, as he has already changed his published anatomical opinions on other questions connected with obstetric anatomy, I have the honour to be,

Your most obedient servant,

ROBT. PATERSON, M.D.

Leith, Nov. 27, 1842.

Letter from Professor Reid to Dr. Paterson.

My dear sir,—As I receive the MEDICAL GAZETTE in monthly parts, and not in weekly numbers, I have not yet had an opportunity of seeing the lecture of Dr. Lee, to which you refer in your letter of yesterday.

I have, however, no difficulty in giving explicit answers to the questions you put to me, in as far as these regard the three preparations which I submitted to your examination when you

were carrying on your researches into the structure of the corpus luteum, and which were described and figured by you in a paper in the 142d number of the Edinburgh Medical and Surgical Journal. The corpora lutea found in these three cases are those marked figs. 3, 4, and 5, in the delineations given in the paper referred to.

I have no hesitation in stating, that I do not entertain the smallest doubt that these were true corpora lutea. No one, I should imagine, who had an opportunity of examining the two last cases, could entertain any suspicion that an embryo was not present in the uterus in both; and though the ovaries were very minutely and thoroughly examined, no other appearance at all resembling a corpus luteum was to be observed, besides those which you have delineated. With regard to the first of these three cases, though no impregnated ovum could be detected, yet altogether, apart from the appearances presented by the corpus luteum, the microscopic examination of the membrana decidua lining the inner surface of the uterus has fully satisfied my mind, at least, that the female from whom it was procured had been lately impregnated.

You are perfectly correct in stating, that we frequently examined together fine sections of the mucous membrane of the uterus in the two first of these preparations, which are still in my possession; that the tubular structure lately described by Dr. Sharpey was distinctly observed; and that these two preparations were among those which I placed at Dr. Sharpey's disposal, when he was investigating the mode in which the membrana decidua is formed. I have also in my possession the uterus of the case which you describe immediately after that furnished you by Dr. Simpson, without giving the delineation of the corpus luteum, and I have also no hesitation in stating, from microscopic examination, that its inner surface was covered with a membrana decidua.

With regard to the question whether or not Dr. Thomson was correct in stating that there was a central cavity in the corpus luteum delineated in Fig. 4, there can be no doubt, as any one may readily satisfy himself by looking at the preparation in my possession, that there could

be none. I feel fully satisfied that all that Dr. Thomson meant by stating that there was a central cavity, (and in this he was perfectly correct,) was, that the true texture of the corpus luteum occupied the surface of the body only, and did not extend through the centre. The yellow plicated structure was confined to the circumference, forming a kind of sac, the centre of which was completely occupied by a reddish-grey coloured fibrinous mass, exactly as you have described it.

Having had the best opportunities of judging of the correctness of the delineations and descriptions you have given of the above cases, it is only an act of simple justice on my part to state, that I am perfectly satisfied of their accuracy. I do not remember whether I had an opportunity of examining the corpus luteum found in Dr. Simpson's case, when in a perfectly recent state, but I had little doubt, from an examination of the uterus, that its inner surface was covered with a membrana decidua.—I remain,

Yours very sincerely,
(Signed) JOHN REID.

University of St. Andrew's,
Nov. 25, 1842.

ON DISLOCATED TENDON OF THE BICEPS.

To the Editor of the Medical Gazette.

SIR,

IN your journal of November 11th, there is a paper by Dr. Knox on the "abrasion of diarthrodial cartilages by friction," in which he comments on a communication of mine published in vol. xxiv. of the Medico-Chirurgical Transactions, and accuses me, or rather Mr. Partridge, in a note which, as he justly observes, is *unworthy* of the text, and, he might have added, of himself, of intentionally concealing the priority of his own observations on dislocated tendon of the biceps.

I should not have allowed two opportunities to pass in the weekly publication of your journal, had I intended from the first to have replied to Dr. Knox's remarks; but it seemed to me that the prejudiced spirit in which they were written was sufficiently stamped upon them to prevent their receiving the attention which is due only to calm

and courteous criticism, and that consequently, although erroneous, they did not merit a refutation; but some friends have considered that, in justice to Mr. Partridge's character as well as my own, I was bound to set Dr. Knox right in this matter.

Not being a member of the Medico-Chirurgical Society, I requested my friend Mr. Partridge to communicate my paper, of which, contrary to Dr. Knox's insinuations, he did not originally write, nor afterwards alter, one single word.

With regard to the woodcut, had not Dr. Knox been wilfully blinded, he must have perceived that the drawing related to the first case, that of Joseph Cooper, in which the tendon is described as *lying on the lesser tubercle of the humerus*; whereas, in the second, it is represented as having slipped over the head of the bone, and *lying at the inner and posterior part of the joint*.

I regret that I did not mention Dr. Knox's paper (published in vol. i. of the MEDICAL GAZETTE, and entitled, "Altered condition of that portion of the tendon of the biceps flexor cubiti which passes into the shoulder-joint"), in my brief allusion to the form of injury of which it chiefly treats; but *rupture* of the bicipital tendon was not the subject of my memoir, and I only gave to it an incidental notice; whereas *dislocation* of the tendon, which it was the object of my cases to illustrate, is not even named in Dr. Knox's paper, although in his recent remarks he says—

"In 1827 I published in the LONDON MEDICAL GAZETTE an account of several dissections of shoulder-joints, which had evidently suffered some severe injury during the life of the person;" and referring to these cases, he continues, "I ventured to draw the conclusion that in some, at least, there had been rupture or dislocation of the bicipital tendon."

I trust this statement will prove to Dr. Knox, that I have not even encroached upon his subject, much less "made use of his property," on which, indeed, one might inadvertently trespass, while the Doctor allows to his claims such extensible limits as appears from the preceding paragraph.

I think it unnecessary, in conclusion, to do more than advert to the captious tone of Dr. Knox's remarks. I attributed it at first to some personal mis-

understanding between himself and Mr. Partridge; but I learn from the latter gentleman that his slight intercourse with Dr. Knox has always been of the most friendly character*.

I am, sir,

Your obedient servant,

JOHN SODEN, Jun.

Bath, Nov. 29, 1842.

CASE OF CHOLERA.

To the Editor of the Medical Gazette.

SIR,

SHOULD you deem the following case worth recording in your useful periodical, its insertion will much oblige

Your obedient servant,

J. COLLIER, M.R.C.S.

Brackley, Nov. 30, 1842.

I was called, on the 10th of October, 1842, to attend David Townsend, a labourer, aged 34, who had been seized about twelve o'clock in the day with vomiting and purging, violent cramps of the legs and belly, with chilliness of the surface. The countenance looked anxious, of a livid colour; the eyes sunk, and surrounded by a dark circle; cold perspiration on the forehead; pulse small, weak, and irregular; tongue clean, moist, and paler than natural; much thirst, and frequently asks for cold water. The evacuations, which were profuse, looked exactly like rice-water or gruel, and the sheet, although saturated, was not discoloured by them.

Viewing this case as one resembling the Asiatic cholera, and having seen three cases similar to it in the neighbourhood (one of which proved fatal on the fourth day), I gave him a full dose of brandy with opium, which remained on the stomach, applied warmth to the body, and the limbs to be constantly rubbed. Calomel and opium, with effervescing medicine, to be taken every two hours.

11th, 8 A.M.—Diarrhœa has ceased, but the vomiting and spasms continue; feels warmer; pulse 100; has not slept, nor passed any urine, since yesterday; bladder not distended. There being

some tenderness of the abdomen, I abstracted sixteen ounces of blood from the arm, which relieved him for a time. The man acknowledged having eaten a large quantity of sloes on the day previous to the attack, which, no doubt, proved to be the exciting cause of the disease. Ordered blue pill and colocyath, with liquor opii sedativus, in a saline mixture, every two hours; an injection of warm water; mustard cataplasm to the stomach.

9 P.M.—The stomach continues to reject the mixture and pills directly they are swallowed, and the consequent collapse is very great.

12th, 9 A.M.—Has not been able to get any rest during the night; tenderness of abdomen increased, particularly over the epigastrium; vomiting continues unabated, and, in addition, there is violent and continued hiccupping: pulse 120, and small. Ordered to continue the mustard cataplasms to the stomach, and injections of warm water per rectum: medicine to be given every four hours, with hyoscyamus and capsicum.

8 P.M.—Decidedly worse; medicines still rejected, nor has any benefit been derived, or the bowels relieved, from the injections: pulse 120. An injection of castor oil and turpentine was now tried in lieu of warm water, which was forcibly retained for fifteen minutes, when it was allowed to come away, but still without success. Directly afterwards two pints of warm gruel, with an increased quantity of turpentine and oil, were again injected, and forcibly retained for twenty minutes, when it came away without any admixture of stool, as all the others had done. He was now taken out of bed, and laid prostrate on the room floor, in a complete state of nudity, when several gallons of cold water were dashed upon the abdomen from a height of several feet. Directly afterwards he was placed in bed, and well wrapped up. The following mixture ordered:—

R. Solut. Magnes. Sulph. ζ viii.; Acid. Hydrocyanci, Mxij. M. ft. mistura sumat. Coch. iij. Mag. 2da quaque hora.

13th, 9 A.M.—Has not vomited since the cold water dash, and commencing the last mixture. Bowels slightly relieved in the night; countenance looks

* We did not like to decline Mr. Soden's letter, but he will perceive that we have omitted one sentence, as it did not appear to us calculated to do any good.—ED. GAZ.

better; pulse 86, and moderately full. Mixture continued, and the following pills in addition:—

R Ext. Coloc. Comp. ʒij.; Hyd. Chlorid. gr. xiv.; Pulv. Opii, gr. ij. M. ft. massa et in pil. xij. dividenda, quarum sumat duas cum singulis dosis misturæ.

8 P.M.—Feels decidedly better; the bowels having been copiously relieved of a quantity of offensive green matter during the day; able to take some tea and gruel with comfort.

14th.—Bowels have been again acted upon; tenderness of the abdomen subsiding; the hiccough continues very severe and frequent. Medicines continued.

15th.—Is considerably improved; hiccough entirely gone, and tenderness of the abdomen considerably better. Medicines continued.

16th.—Continues improving.

18th.—Tenderness of abdomen entirely gone; stomach perfectly tranquil; bowels moved. A large vesicle has made its appearance where the cataplasm was applied, together with eruptions, which are very tender and painful, caused probably by the frictions that had been used. To apply common poultices.

21st.—Convalescent. Ordered a mixture of Quina c. Infus. Aurant. Comp. ter dies sumend. To have mutton-chop, and wine, &c.

28.—He gradually gains his strength, but is still very weak. Perstat.

Nov. 8th.—Able to come to the surgery, a distance of four miles.

25th.—Has resumed his usual occupation.

ON THE PERFORMANCE OF TONSILOTOMY*

IN THE
ANGINOSE VARIETY OF SCARLATINA.

By JAMES YEARSLEY, Surgeon.
(For the London Medical Gazette.)

SINCE the introduction of vaccination, scarlatina, which we formerly held as secondary in importance to small-pox, has gradually advanced from this posi-

tion, and may, probably, now that the Vaccination Act has come into operation, be considered as the most formidable of all the exanthemata. Whether this has arisen from any increased severity in the nature of scarlatina itself, or whether it happens from the circumstance of a large number of delicate constitutions, which formerly would have fallen a prey to its ravages, being now left to the inroads of other diseases, among which scarlatina is one of the principal, it is not my object at the present time to inquire. I am desirous of drawing the attention of your readers to one of the most serious lesions occurring in the course of the disease, with the hope of suggesting a mode of treatment that may moderate, or, in some cases, remove the danger.

Much importance has always been attached to the throat symptoms, but latterly the formidable character of this complication, or rather integral part, of scarlet fever, has been more than ever insisted on. In the anginose variety, it is well known to be one of the earliest, and throughout the most marked and dangerous part of the disorder. The evils produced by the throat disorder are difficulty of swallowing, violent cough, disturbance of the cerebral circulation, so as to cause severe headache or even delirium, and the patient is distressed beyond measure by the continued effort to expel the glutinous secretion which collects about the fauces. The inflammatory condition, without doubt, affects the whole of the throat, but I am of opinion that engorgement of the mucous membrane, and enlargement of the tonsils, have the most considerable share in producing the swelling, irritability, and morbid secretion. It is this fact which brings me to the point of the present paper.

I fully believe that children who suffer to any extent from chronic enlargement of the tonsils are *cateris paribus* very much more likely to fall victims to scarlatina than those in whom a healthy state of throat exists before the accession of the fever.

Many observations on my own part, and inquiries among my medical friends, have convinced me of the truth of this position. The inference deducible is plainly evident. Children suffering from enlarged tonsils, who

* *Tonsilotomy*—a term proposed by the author of the paper to designate excision of the tonsils.

have not had scarlatina, ought to receive prompt and careful treatment, with a view to remove these enlargements. I believe that life might often be saved by their excision. A case lately occurred within my knowledge, in which scarlatina attacked a child so circumstanced. The fauces became entirely blocked up, and the patient died from suffocation. It is an everyday occurrence. A provincial surgeon was consulted in two cases of enlarged tonsils; an early day was appointed for their excision; before the day arrived, scarlatina attacked every member of the family. All did well except the subjects of the enlarged tonsils: they died. It is from facts such as these that I am induced to recommend the trial of excision at any period of the fever. To say the least of such treatment, it offers quite as good a chance as laryngotomy does, in obstruction of the larynx. It must be borne in mind that strangulation from closure of the fauces often happens as a purely local affection, while impediments to the passage of air through the larynx are generally complicated with bronchial or pulmonary disease, which materially lessens the chances of the success of an operation.

From the rather exclusive nature of my own practice, I have not as yet been able to test the success of tonsilotomy in scarlatina, and although, through the kindness of many medical friends, opportunities will probably immediately be afforded me of verifying or annulling the views here developed, still the prevalence of scarlatina at this moment scarcely justifies me in withholding those views, strengthened as they are by cases greatly analogous.

Some time ago it fell to my lot to show to the profession generally that which was previously known among them to a very limited extent; namely, that tonsilotomy, in ordinary circumstances, might be performed with perfect safety, almost without pain, and without hæmorrhage, generally not a teaspoonful of blood escaping. More recently I have had cases of catarrh, and severe sore-throat, where enlarged tonsils were present, acutely inflamed, and threatening suffocation, in which excision probably saved the lives of the patients, and in which also, the loss of blood was no more than, under the circumstances, was desirable. I consi-

der it therefore as proved, that enlarged tonsils may be excised, even when acutely inflamed. And it is this fact which led me to believe that the operation will be of eminent service in the anginose variety of scarlatina, when the urgency of the throat symptoms endangers life. To the forms of rubecula, in which the throat becomes affected, it may be equally applicable, as well as to the early stages of that disease, cynanche laryngea, in which tonsillary inflammation and enlargement is frequently the first symptom.

I may sum up by observing—1st, that the presence of enlarged tonsils is an important source of inconvenience and danger in all affections of the throat, especially in scarlatina, and more particularly in scarlatina anginosa, its most fatal variety; 2d, that it would be a great preservative against the mortality of scarlatina, if tonsillary enlargements were always removed either by medical or surgical means from children, and even adults, who have not passed through this fever; 3d, that where this has not been done, the danger may be in great measure obviated by performing tonsilotomy during the actual presence of scarlatina, or any disease of the throat threatening suffocation, and that no injury whatever is at all likely to follow the operation, if performed under these circumstances.

Such facts as I may be able to collect, whether favourable or unfavourable to my views, shall, with your permission, be laid before your readers in another and an early communication.

15, Saville Row, Nov. 29, 1842.

ANALYSES AND NOTICES OF BOOKS

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

A Practical Treatise on the Human Teeth; shewing the Causes of their Destruction, and the Means of their Preservation. By WILLIAM ROBERTSON. 3d edit. London, Churchill. pp. 224.

THE fact of a book having gone through three editions is not a trilling argument in its favour; for we hold it to be unusual for a medical work to have a legitimate sale to such an extent without

some inherent merit to sustain and recommend it.

As its title-page signifies, this work is purely a practical one, having for its object a very simple elucidation of the cause and prevention of caries. Though there are many interesting anatomical and physiological observations throughout its pages, the volume is chiefly, and most importantly, occupied with a discussion of the nature and treatment of the diseases to which the teeth are liable. Prior to the appearance of the first edition of Mr. Robertson's treatise, in 1835, the prevailing opinions concerning caries of the teeth were those of Fox and Bell; the former maintaining that the disease consists in an inflammation of the bony substance of the crown of a tooth, which secondarily affects the lining membrane of the organ, causing its separation, and a consequent decomposition of the solid parts; the latter insisting that caries commences in inflammation of the bone immediately under the enamel, from which, he says, the tooth, owing to its imperfect vitalization, cannot recover, and death and decay are the consequence.

Mr. Robertson, on the other hand, maintains that the remote cause of destruction of the teeth is the decomposition of food which lodges in the interstices between them.

The inflammatory theory, then, is to the effect that the teeth decompose by vital action, commencing in their interior, and proceeding to their surface. Our author's theory is exactly the opposite, namely, that decay begins by chemical action upon the surfaces of the teeth, and proceeds to their interior, and that inflammation is the consequence, and not the cause, of caries. His arguments are chiefly derived from the fact, that the teeth decay only in such situations as are favourable for the lodgment and decomposition of food, and never upon their smooth and even surfaces: from their decaying in pairs, and at particular periods of life; from the ready relief which filling and filing afford, if decay be not too far advanced; from the disease commencing externally and proceeding inwards, and never conversely; and from the circumstance, that artificial teeth are liable to the same species of destruction as natural ones.

These arguments we apprehend to be

perfectly sound, and in accordance with the rules of common sense and experience: for we cannot imagine a disease, which owes its origin and progress to inflammation, to be susceptible of alteration or cure by means which, of all others, are most calculated to contribute to such action. But when the cause is purely chemical, and owing primarily to a defect of structure, it is not irrational to suppose that mechanical treatment will arrest or remedy it. It is on this ground that we think the practical application of Mr. Robertson's theory particularly valuable. Believing, as he does, that inflammation is not the cause of caries, but the consequence of it, and dependent upon the influence of atmospheric and other agencies upon the lining membrane of a tooth, he urges the necessity of removing any decay that may be apparent, *before the occurrence of pain*; for after its commencement there is little hope of a permanent remedy. He insists upon the propriety of constantly using a tooth-brush, so that any particles of decomposing food may be removed; and of an occasional inspection of the teeth by a dentist, that any lurking decay may be arrested. He tells us that these suggestions have wrought a considerable change in his own practice—that people now apply to have caries arrested, rather than to have teeth removed in consequence of its ravages; and he maintains that, if this plan were universally acted upon, tooth-ache would be comparatively unknown, and the organs would be preserved in beauty and usefulness to the remotest period of life.

We cannot but concur in our author's theory, and we cordially recommend the work to all who may feel interested in its contents.

MEDICAL GAZETTE.

Friday, December 9, 1842.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestis modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

PRESENT STATE OF PRISONS.

"ROME," says the adage, "was not built in a day;" and it would appear,

from the Reports before us*, that prison discipline cannot be built up in half a century. Since the time of Howard, the state of our prisons has constantly occupied thinking men; yet, in many instances, it is still below any thing which could have been reasonably anticipated. We do not speak of small faults,

quas aut incuria fudit,
Ant humana parùm cavit natura,

but of huge enormous defects, piled upon one another, like Ossa upon Pelion. And, though so palpable and so flagrant, that to be hated they need but to be seen, in many places they are continued from year to year, in spite of exposure and remonstrance—here to save fifty pounds, and there to gratify some crank of the visiting magistrates. Among the strange things still existing, we may mention damp ill-ventilated cells; the use of chains, rendered necessary by the insecurity of some jails; and diet tables far below scurvy point. Captain Williams, in his Report on the Northern and Eastern District, has some just observations on the diet of prisons. It is commonly assumed that the diet of a House of Correction should be inferior to that of the labouring population of the neighbourhood. Accordingly, in agricultural districts, where the poor eat very little meat, the prison dietary contains less, or sometimes none. But how great is the difference between the ploughman, with the sky above and the breeze around him, enlivened by cheerful intercourse with his fellows, and indulged with a certain choice in diet and action, and the same man pent up in a cold narrow cell, depressed by admonition and coercion, and left with a pound of oakum for his companion! Why, beef and ale would scarcely bring up such a

prisoner to his out-of-door level! A long course of bread and gruel is followed by diarrhœa and scurvy.

“I scarcely recollect,” says Captain Williams, “an instance of scurvy being prevalent in a prison, but where it might be distinctly traced to a want of variety in the diet, and its deficiency in nutritive qualities.”

The reason, of course, which has brought prison dietaries so low, has been the fear of encouraging crime by too comfortable a mode of living, in the place of punishment. But though this danger is not to be lost sight of, it is by no means an imminent one; the rustic culprit regrets the liberty of ranging over hill and dale; while your town thief would not exchange the fetid luxury of Dyot Street for the nitid walls and spotless floors of the most exemplary prison.

In some jails the diet is so destructively low that it obviously cannot be adhered to in long imprisonments. Thus, in the Derby County Jail and House of Correction, the daily allowance is 24 ounces of bread, four ounces of oatmeal made into two quarts of gruel (one for breakfast, and the other for supper), and one pound of potatoes for dinner, and half an ounce of salt. It is clear that this dietary is in direct contradiction of the 11th rule of the 4th of Geo. IV., which enacts, “*that every prisoner shall be allowed a sufficient quantity of plain and wholesome food.*”

This starving code is practically mitigated by the surgeon, who commonly orders a quarter of a pound of meat (daily?) for those who have been ten months in the prison; but every one will agree with Capt. Williams, that the diet-table ought to be re-constructed. In the Lincoln City Jail and House of Correction, sea-scurvy made its appearance among the prisoners. A woman,

* Seventh Report of the Inspectors of Prisons. II. Northern and Eastern District. III. Southern and Western District. IV. Prisons of Scotland, &c. Presented to both Houses by Command of Her Majesty. 1842.

for example, had swelling of the gums, petechiæ, and an almost insupportable odour from the mouth. She was pardoned, and removed to the Union work-house, where she died. A man had petechiæ, with both urine and stools bloody. Another man was in the last stage of debility, and seemed unlikely to recover; but his life was saved by placing him in the grand-jury room of the Sessions House. At the expiration of his sentence he was removed to the Union, where he was able to work at his trade of a tailor.

Dr. Cookson, who examined the prison at the request of the magistrates, attributes the presence of scurvy to three causes—the situation of the jail, its bad construction, and the diet. So wretched is the arrangement of this jail, that one only of the felons' sleeping-rooms has a casement window and a fire-place: in the other cells "there are no fire-places, nor even apertures for the escape of contaminated air: one of them, in which there are three beds, measures 9 feet 7 inches by 7 feet 9 inches—an area too limited to be healthy, even for one occupant, without a free influx of fresh air, and a means of escape for the product of respiration." The dietary, though not good enough to enable the prisoners to struggle against other depressing influences, is certainly better than in many other jails. It consists, or consisted, of a small portion of boiled beef four times a week (twice fresh, and twice salt), with bread and farinaceous vegetables. On the other days, they had the broth thickened with oatmeal.

Besides improvements in the ventilation of the prison, Dr. Cookson suggested several changes in the diet, among others the use of fresh vegetables, especially those of the cabbage class, and the disuse of salted meat. Mr. Kent, the surgeon, had previously found fault with the want of ventila-

tion, and the monotony of the diet. It is not stated whether these recommendations have been attended to.

From the report on the southern and western district, drawn up by Dr. Bisset Hawkins, it appears that the prisoners in Monmouth County Jail have 24 ounces of bread daily, together with a pound of potatoes, and four ounces of oatmeal; which is precisely the famishing scale of Derby! Those at hard labour, however, have 24 ounces of potatoes in addition, daily. In consequence of this wretched allowance, the surgeon was obliged to order extra food to a number of the prisoners. In one quarter the sick diet amounted to £16. 5s. 1d.; whereat the magistrates grumbled considerably.

A remarkable circumstance is mentioned by Mr. Hill, in his report on the prisons of Scotland, clearly shewing the unspeakable misery to which the indigent are reduced there, for want of a Poor Law. *In the prison at Glasgow, there are about fifty voluntary prisoners.*

These persons have committed no offence, and have spontaneously subjected themselves to all the rigour of imprisonment on the separate system, to obtain food and shelter.

"Some have been in this kind of civil death for more than a year, giving up every particle of personal liberty, performing a task of ten hours' labour every day, before they can earn a penny for themselves, living on very plain food, rising early in the morning both in winter and summer, and many of them confined day after day, and month after month, in a small cell apart from all human beings, except the officers of the prison; and this with the knowledge that at any moment they have but to utter a word, and they can be placed at perfect liberty."

A difficult question constantly arises in the economy of prisons, namely, how is order to be preserved in them? If prisoners are riotous and disorderly, tear their clothes, and refuse to do their

work, what punishment should be inflicted? The allowance of food is commonly so small, that it can rarely be right or expedient to diminish it. Of the remaining punishments, the principal ones are solitary confinement and whipping, either of which may be properly employed, if confined within due limits, but the former alone being applicable to females. The usage varies much on these points in different prisons, and it would be but just to make it more uniform. Thus in the Sixth Report we find that in the Bedford House of Correction the usual punishment for prison offences is confinement in the refractory [cell] or in the culprit's own cell, varying in length from four hours to one day. In one instance, however, three days in the "Refractory" were the punishment for destroying the prison clothes; and in another, a week's solitary confinement was inflicted for destroying the bed-clothes.

On the other hand, in some prisons, one, two, or three days' solitary confinement appears to be the common punishment for prison offences; nay, in the Northallerton House of Correction, we find three days' solitary confinement inflicted on *untried* prisoners for such offences as "talking several times," "talking and laughing constantly in the work-room."

No judicious person will deny that so formidable a punishment as solitary confinement, when protracted beyond a day, should be inflicted only by high authority, and that even then its limit should be defined by the legislature. Probably seventy-two hours would be sufficient in the worst cases, and should be reserved for the worst alone. Even when this punishment is inflicted by the sentence of a court of justice, three continuous days might be enough: the prisoner sentenced to three months' imprisonment might spend three days occasionally in solitude, and the rest of

his time in working under *surveillance* with his fellow-sufferers. But such a method should be strictly reserved by the legislature for heavy crimes, else it might be inflicted by country magistrates on offenders against the game-laws.

In whipping, the greatest diversity prevails throughout England. Thus, in Appleby County Jail and House of Correction, "corporal punishment is rarely inflicted: the only recent instances are of two boys who were flagellated with a rod."

At Northallerton, the whipping is generally two dozen lashes, or fewer if the surgeon thinks proper. At Beverley, the usual number is thirty; one of the scourges was thought too heavy by Capt. Williams, and was destroyed in his presence. In Kingston-upon-Hull Jail, the whipping is described as sufficiently severe, but not so as to incapacitate the sufferers from labour. Here, again, one of the scourges was destroyed in Capt. Williams's presence. The chief turnkey says, in his evidence, "never more than three dozen is given"; but it is scarcely clear from the context whether the punishment of boys or men is spoken of.

In the House of Correction for the West Riding at Wakefield, there is no flogging for breaches of discipline; and "whipping by order of court is generally inflicted on the day of discharge. The number of lashes is from thirteen to twenty-one. The higher number is given to those who are sentenced to be *severely* whipped."

In Derby County Jail, the number is generally forty lashes.

In Nottingham County Jail, the only punishment has been that of two boys with a birch rod.

Again, in the Southwell House of Correction (Nottinghamshire), a man received fifty lashes for refractory conduct; while, in the House of Correction

for the division of Lindsey, at Kirton, in Lincolnshire, the surgeon generally interferes after twenty.

In the Spilsby House of Correction for the division of Lindsey, in Lincolnshire, Capt. Williams informs us that the "whipping is described as being severe; it is inflicted by one of the turnkeys, in the presence of the surgeon. I examined the scourges, and recommended that they be of a less severe make."

It is needless to pursue this subject into farther details. In one place the usual number of lashes is 11, in another 25; and a writer in the *Times*, who had minutely examined all the Prison Reports with a view to this subject, found that in one jail the usual punishment was fourteen dozen lashes!

It is obvious that both the number of stripes, and the nature of the instrument with which they are inflicted, should be fixed by authority. It is impossible, perhaps, in the present half-civilized state of society, to dispense entirely with the scourge; but it is absurd and unjust that the punishment for the same offence should vary from a school-boy flogging to a military laceration, according to the whim of eastern or western magistrates.

ST. GEORGE'S HOSPITAL.

Successful Operation for Strangulated Hernia, at the age of 107!

We do not know that there is any record of the performance of a severe operation at the advanced age of 107, which has, however, been performed by Mr. Cæsar Hawkins, with success, in St. George's Hospital; and we apprehend there is no doubt of the patient's real age, as the certificate of his birth has been preserved by his friends, one of whom came with him to the hospital, and asserted that he had seen it. The patient is, moreover, well known as a musician, who had the honour, as he expresses it, of playing on the violin with his late Majesty, George the Fourth. His name is Rochard, a French-

man, and his faculties are quite entire; he was able to walk into the ward, and within these few days was strong enough to walk from Bayswater to Charing Cross, and back again.

This man came to the hospital about one o'clock on Thursday last (Nov. 24th) with strangulated inguinal hernia, which had been fixed from, at least, the previous morning, and perhaps for a longer time, as no motion had passed for three or four days: the tumor was hard and tender, and vomiting had repeatedly taken place, but the countenance was cheerful, and the pulse unaffected.

While some other operations were being performed, Mr. Hawkins informed the students of the case having been admitted, and said that two attempts to reduce the hernia had been made before his admission; that the muscles being at his age completely relaxed, the only remedy likely to be useful was the application of ice, which he thought not unlikely to diminish the size of the tumor enough to enable it to recede, and that as the symptoms were not severe, and were generally slow in their progress at an advanced period of life, he would give him this chance, and see him again at five o'clock. When Mr. Hawkins came, however, at this period, he found that although there had been no sickness, yet the tumor was rather more tender, and therefore proceeded at once to the operation. The sac was very thick, and on opening it a mass of apparently transparent jelly protruded, which was a considerable quantity of recent lymph, distended with the serum, which filled the sac: the contents were a few inches of inflamed small intestine glued together and to the sac by lymph, which Mr. Hawkins was obliged, after dividing the stricture, to tear away from the bowel in order to reduce it. The case went on very well afterwards, and requires no particular notice;—evacuations were passed the next day, after an injection;—some slight tenderness of the abdomen was relieved by chamomile poultice, and by one or two doses of calomel on the Saturday. The wound united entirely by the first intention, except where two ligatures had been applied to a divided vessel of the outside of the sac, which part was slightly opened by the probe: the last section was removed on Sunday, and on Wednesday, the 30th, we saw him sitting up in a chair. We may observe that nourishment was given him from the first, and a little wine the last day or two; he is rather weaker since the strangulation, but appears to be going on quite satisfactorily.

Dec. 7.—Continues to go on favourably in every respect; in fact, he may be regarded as having entirely recovered.

THE MARYLEBONE INFIRMARY.

Sloughing of the scrotum.—Case of popliteal aneurism.—Curious case of femoral hernia.

J. T., aged 52, was admitted into the St. Marylebone Infirmary, under the care of the physicians, with symptoms of cerebral disturbance. He had, on a previous occasion, been under treatment with similar symptoms. On the third day after admission it was accidentally discovered that there were gangrenous spots on the scrotum.

On the day these sloughs were discovered he was sent down to a surgical ward, and was seen by Mr. Phillips, who found him heavy, stupid, and unable to give any information as to the sensations he had experienced, or as to the time when inflammatory action had set in. He was carefully examined: the scrotum was very tumid, of a dusky red colour, tense, and three or four times its natural bulk, with two sloughs, each larger than a shilling, and of a dark colour, at its most depending part; the perineum was equally red, equally tense, and presented all the appearances of infiltration of urine. His own account of himself did not make it very evident whether he had made water on that or the previous day, or whether he had stricture. A No. 4 elastic gum catheter was passed without much difficulty into the bladder, and about two ounces of high-coloured urine dribbled away through it. This circumstance made the nature of the case more doubtful; but still the course of action was sufficiently clear. Two longitudinal incisions were made alongside the raphé—they were deep enough to pass through the superficial fascia; and similar incisions were made through the tegument of the scrotum. Through these incisions a quantity of urine-like fluid escaped, tinged with dark venous blood: it amounted, in six hours, to upwards of a pint. Warm fomentations were kept applied upon the parts, and he expressed himself as much relieved. Gin and water was ordered for him; but he died comatose on the succeeding day.

He was examined after death. The cerebral symptoms were accounted for by the existence of softening, and considerable effusion under the membranes of the brain: the bladder and urethra, together with a portion of the pubis, were removed, and the parts were very minutely examined. The bladder was moderately healthy, the urethra quite so, and there was no breach of surface at any part of its course. During life, Mr. Phillips expressed an opinion that the head symptoms, for which he was sent to the physicians' ward, might have been a con-

sequence of urinary disease; but then the little urine contained in the bladder after death was not albuminous, and it is clear that there was no retention to account for the cerebral disturbance. It subsequently appeared that on a previous occasion he had been treated for cerebral disturbance, and no doubt the same condition had rendered him so indifferent about the perineal mischief, as only to have directed attention to it on the day on which he was placed under Mr. Phillips' care.

The affection in question has been described by Mr. Liston, in a paper contained in the Transactions of the Royal Medical and Chirurgical Society, as an "acute form of anasarcaous tumor of the scrotum:" whether the disease does not come more nearly under that condition known as erysipelas phlegmonodes, may be matter of question. In Mr. Liston's cases there had been some local injury to excite it; in one case an abscess near the verge of the anus; in another a kick on the perineum by a cow; in another inguinal fistula; in another a gun-shot wound, and the infiltration was principally confined to the scrotum.

In the present case the infiltration extended along the perineum into the tissues of the scrotum, and sloughing had followed, while there was no apparent exciting cause.

Popliteal aneurism.

—Daly, æt. 53, was admitted into the St. Marylebone Infirmary with a diffused popliteal aneurism on the right side, which had already produced some oedema of the right foot. His account of it was, that he had discovered a swelling in the ham three weeks before admission, that it had rapidly increased in size, and become very painful, especially at night. There was so much general irritability, and so much arterial action, that it was thought advisable to delay the operation for a few days, in order to try the effects of such means as were likely to improve his condition with reference to those symptoms. For some days, the treatment employed for this purpose (namely, careful diet, quiet, and digitalis) had a decidedly good effect, but the pain in the ham, after that, increased, as well as the girth of the limb. Under these circumstances it seemed unwise to delay, and the patient did not object to the operation, but when all was prepared, his courage failed him, and no persuasion could move him to submit to it. Several days passed, the pain increased, the size of the limb also, as well as the oedema; and he then proposed that the operation should be performed. Lest his courage should ooze away again, the operation was at once proceeded with, though the circumstances were any thing but favourable—an habitually intemperate man, with gene-

rally excited arterial action. When laid upon the table, the femoral artery appeared to be very superficial, for its pulsation could be perceived from Poupart's ligament to near the edge of the sartorius muscle. An incision of the usual extent was made, but it was found that instead of being so near the surface as had been supposed, the artery was deep-seated. At the edge of the sartorius muscle Mr. Phillips perceived an artery about the size of the facial, under which he passed an aneurismal needle, upon which it was raised, and while so separated from surrounding parts Mr. Samwell and Mr. Stafford satisfied themselves that it was an artery. A ligature was drawn under it, but for the moment it was not tied. Before the sheath was opened, another artery of the same size as the former was discovered, and treated in the same way. The sheath was now opened, and a ligature placed around the femoral trunk, which was of large size. The latter ligature was tightened, and the pulsation in the tumor cut off. The branches were then carefully looked to; one of them was found to arise from the femoral, about half an inch above the sartorius; the other arose somewhat higher, and apparently from the profunda. A question then considered was, whether the common trunk should be tied above the points where those arteries were given off, supposing both to arise from the femoral trunk, or whether those two branches should be secured by the ligatures already around them. Seeing that the artery was tied, seeing the uncertainty of both being given off from the femoral, and seeing, further, that it was uncertain how near we might be to the profunda, Mr. Phillips at once secured those two branches. The wound was brought together by sutures, and covered with wet lint; the patient was put to bed, and the state of the limb was fully noted for six hours, but there was no sensible change of temperature, neither was there during the succeeding days: this was probably owing to the size of the tumor and the condition of the artery, which had already interfered so far with the circulation as to establish it in the collateral channels. The patient's suffering was lessened from the moment of the operation; the pain in the tumor was dissipated, and in forty-eight hours his general condition, and his countenance, were much improved; but the irritability of the pulse, and the excited action of the heart, underwent little change until the third day, when he began to take meat and beer. At this time there was only one thing to create uneasiness, and that was the large quantity of blood effused at the ham and the upper part of the calf. On the eighth day there was heat, and some redness, apparent at that part, and evaporating lotions were applied, but they did not remove

it. On the eleventh day fluctuation was evident, produced, it was supposed, by the breaking down of the coagulated blood: for the purpose of testing this an exploring needle was passed into the ham, and some dark, red, thin, bloody fluid escaped, containing, as was conceived, pus. It was examined under the microscope, and pus globules were found in it. Two incisions were then made to allow of the escape of this fluid, but the quantity poured out was not great; a poultice was applied to the part, and as the mass broke down it escaped. The irritation set up at the point by the breaking down of so large a mass was great, and it ended in gangrene; the region being in a very apt state for such a termination, from the unsatisfactory state of the circulation there. The gangrene extended, spite of all the means used for arresting it, and spite of the stomach bravely bearing up; and the only question still open was that of amputation above the knee; but as the man's general condition was unfavourable, as the gangrene was spreading, and as the circulation immediately above the knee was not satisfactory, and as a similar state of things might be produced on the stump, it was determined not to propose it. As the discharge from the leg was becoming profuse and foetid, a lotion of decoction of bark and chloride of lime was substituted for the poultice. Much was hoped from the integrity of the stomach, which allowed of his taking two chops, four ounces of brandy, and six ounces of wine, daily, but this only postponed the fatal termination, which did not occur until the forty-third day after the operation. The first ligature came away on the ninth day, the second on the thirteenth, and the third not until the thirty-first day.

Being an Irishman, no facilities for making a careful examination were afforded; the artery at the part where the ligature was applied, as well as the parts from the ham, were removed, but they were so broken down by gangrene that nothing could be made of them.

Strangulated Hernia.

An old woman, aged 73, was admitted into the Marylebone Infirmary, under the care of Mr. Phillips, with strangulated hernia. The history of this case shewed that the symptoms of strangulation had been present eight or nine days, though they had not been very pressing; there had been no stool for eight days. Upon examination after admission, the tumor, which was not large, was found to occupy the right femoral region. There was not much tenderness at the point, nor at any part of the abdomen; there was very slight tympanitis; there was some nausea, and occasional vomiting, but not severe. The tongue

had a slight coating; the pulse was 84. Mr. Phillips pointed out that in people advanced in life it is often not prudent to wait for more decided symptoms, because the powers of life are incapable of developing them; and because it is matter of observation that they often die with symptoms which, according to the language of works on surgery, would not warrant a recourse to operation.

As it was ascertained that the taxis had been employed for an hour and a half on the previous day, it was not thought prudent to persevere long in any further attempt at reduction, and the operation was at once had recourse to. An incision was made in the usual way, and the approach to the sac was cautiously made. A tumor, apparently omentum, and much larger than a pullet's egg, was exposed; it was invested by a membrane which was conceived to be the sac: this was opened, and the director being placed under it, it was incised upwards and downwards to such an extent as was necessary. The omentum-like mass was now fairly seen; it was very vascular, and a large number of veins on its surface appeared so tortuous as to give the impression that they were varicose. The tumor was turned up, but no intestine could be discovered under it: there was no reason to doubt that it was an omental hernia. A director passed very easily under Poupart's ligament, and the opening was enlarged to the necessary extent. The tumor was then readily passed back under the ligament. Dr. Boyd and one of the assistants passed their fingers under the ligament, and were satisfied that the reduction was complete. The lips of the wound were brought together by suture, and it was ordered that the patient should be left without medicine for six hours. At that time, as there had been no stool, the house-surgeon ordered a common enema, which brought away a certain quantity of fecal matter. In the night she took three grains of calomel, to be followed in the morning by a beef-tea injection: they brought away a little more fecal matter, but stercoraceous vomiting came on, and in the course of the day she sank.

The body was examined fourteen hours after death. There were very slight traces of peritonitis. The examination was then confined to the neighbourhood of the disease. The tumor had again protruded, and a portion of intestine was involved in it: five or six inches of intestine on either side of the part implicated were removed, together with the tumor, and the following state of things was revealed. The tumor was very condensed and very vascular, having much the appearance of inflamed omentum; it was surrounded by a tolerably dense investing membrane. Into the centre of this tumor a knuckle of intestine passed to the depth of rather more than an inch and a quarter, and on every side

the intestine was surrounded by fat to the depth of more than a quarter of an inch: the pressure upon any part of the intestine did not appear to be great; there was, however, considerable thickening of the peritoneum at the proper neck of the sac, which was hard and unyielding. The intestine was adherent to the sac, as was the sac to the fatty mass. In this case, to which Mr. Phillips knew no parallel, it would seem that the fatty tumor must have been seated in very immediate relation with the femoral ring, probably blocking it up, and that when the protrusion of intestine took place, rather than give way, the tissue of tumor had admitted the intestine to pass into its centre. Of course the proper sac was not opened, and indeed could not have been got at without cutting down half an inch into the tumor.

ACCOUNT OF A
NEW PERCUSSION INSTRUMENT
FOR INVESTIGATING THE DISEASES OF
THE CHEST.

By C. J. B. ALDIS, M.D.

Being an Extract of a Lecture delivered
Nov. 28, 1842.

THE subjects of percussion and auscultation are of great importance; for by employing these methods of diagnosis you will be able to distinguish with precision various diseases of the chest, and by their neglect some important lesion of the lungs may be overlooked, which it will be your duty to endeavour to detect, in order that you may apply the appropriate remedies. Besides, when you recollect the frightful ravages which pulmonary affections make among mankind, a fact rendering such diseases of the highest importance, I need scarcely say more to stimulate your attention to these means of diagnosis. I therefore hope that you will reflect upon the value of percussion and auscultation, the former of which will occupy us in the present lecture, and continually practise them.

Method of percussing.—Some practitioners percuss with the fingers of the right hand, their extremities being in the same line, and in a state of demiflexion, striking the chest in a perpendicular direction. Others employ four fingers of the right hand to strike the fingers of the left hand applied to that part of the chest under examination. Piorry invented the plessimeter, a round piece of ivory, to be placed on the chest and struck by the fingers, for the purpose of preventing the pain likely to be felt by some persons when the parietes of the chest are percussed. Subsequently a light hammer, having a leathern face, was brought into notice, the ivory plessimeter being

struck with it by the right hand. More recently another instrument has been introduced: a handle is attached to the plessimeter, which is struck by a hammer held in the right hand.

Although percussion may seem a very simple operation, still it requires much practice, and many precautions are to be attended to. Now it is very requisite that you should produce equal sounds in comparing the opposite sides of the chest, for the slightest inequality in percussing will produce a difference in sound; and even on examining one side of the chest, we cannot place much reliance on unequal sounds.

About five years ago I constructed a rough model of an instrument in wood, with

a hammer attached to it, having a spring handle, to be raised by the right hand; but I abandoned it in consequence of being in the habit of percussing the chest with my fingers. More recently, however, I made an outline of this instrument on paper, and thought that, by means of a regulator, its elevation might be so managed as to produce uniform sounds; for, on raising the hammer, it falls immediately the spring handle touches the regulating screw, which is moveable when it may be desirable to effect a greater or less elevation of the hammer, in order to produce greater or less uniform sounds. Messrs. Philp and Whicker, late Savigny, of St. James's Street, made the instrument for me.

The plessimeter (see engraving) is made of leather, moving upon a swivel to adjust itself to the part. The percussor is attached to the stem of the plessimeter, and acts

upon a joint. By pressing down the handle of the percussor, the spring throws the percussor down upon the plessimeter, the force of the blow being regulated by a screw.

CONSTIPATION FOR FORTY-FIVE DAYS.

DR. JAMES JOHNSON related the following case, which had terminated fatally that day. The patient, a medical man, about forty-five years of age, had resided in London about eighteen months, with the intention of practising there instead of in the country. Until forty-five days ago he suffered only from occasional spasms of the bowels, the spasms having nothing peculiar in them. His bowels were regular. During the last forty-five days of his life there was no evacuation whatever from the bowels, although every means had been resorted to by Mr. Lane and Dr. Sims to produce such action. About a fortnight before death he (Dr. Johnson) joined in consultation. The patient had then severe spasmodic pains in the abdomen, with almost constant vomiting. His stomach seldom retained anything: the ingesta being either brought up immediately, or two or three hours after being swallowed. None of the matter, however, vomited up, exhibited the slightest stercoraceous character. To afford relief, croton-oil, bleeding, and croton-oil injections, were used, among other means, and Dr. O'Beirne's tube, which, however, could not be passed up any distance, and seldom more than half a pint of fluid, and never more than a pint, could be injected. During the whole of this time the distension of the bowels increased, and his extreme

sufferings were only occasionally relieved by the internal use of opium, and by opiate frictions over the abdomen. Five days before death, at his own urgent request, half a pound of fluid mercury was administered to him. This produced no perceptible effect at the time, but the next day he was seized with spasms in the abdomen. The constipation remained. On one occasion his agony from the distended abdomen was so great that he begged it might be punctured to give him relief. He died on that morning at eight o'clock, and at four in the afternoon of the same day the body was examined. The tympanitis was enormous. On opening the abdomen there were scarcely any signs of inflammation having existed; there was no effusion, and the convolutions of the intestines were not adherent to each other. The dilatation of the intestines was very great; the colon was as large as the colon of a horse, and the other intestines were of proportionate magnitude. The diaphragm was thrust up to a remarkable height, and the stomach was so contracted that it was discovered with difficulty. The gall-bladder contained a few drachms of bile. On following the intestines nothing was discovered but wind. Not the slightest trace of the quicksilver which had been swallowed five days before could be seen, but in the sigmoid flexure of the colon was a dark, tarry-like substance, having a very peculiar odour, but neither in appearance nor in smell like a fecal collection. No globules of mercury could be

detected in it. The cause of the obstruction was found at the junction of the sigmoid flexure with the rectum, in which situation was a dense white scirrhus, surrounding the intestines for the space of three-quarters of an inch, and so completely closing the passage, that although the colon above was enormously distended with flatus, not the smallest quantity of air could be made to pass the stricture. The case was remarkable, from the cause of the forty-five days' constipation being *disease*. When constipation was a habit the bowels might be inactive for a longer period, but he (Dr. J.) had never before known such protracted constipation dependent on disease. The longest period, under such circumstances, that he had witnessed, was eighteen or twenty days at most. It was curious that no sign of the quicksilver, beside that mentioned, could be discovered. He suspected that during the five days that the mercury was in the intestines it had been converted by their convulsive action into the ointment-like substance referred to. It was also singular that the mercury produced no effect on the mouth or breath. Another remarkable circumstance was the absence of difficulty in passing the motions until the setting in of the constipation. The scirrhus must have been going on for years.—*Lancet*, Nov. 26.

ON THE
MORTALITY OF CHILDREN
AT THE
MILITARY ASYLUM, SOUTHAMPTON.

THE Royal Military Asylum was founded for the reception of the orphans of soldiers, and the branch at Southampton was opened in October 1817, for the reception of the younger male children of the parent institution. In 1825, the boys were removed to head quarters, and the institution at Southampton was exclusively appropriated to girls and to boys under seven years of age. In 1835, the admissions were greatly restricted, with a view to the ultimate abolition of that branch of the asylum, and the few remaining children were ultimately removed to Chelsea in November 1840.

For a period of eighteen years, from October 1817 to October 1835, there were admitted 5,427 children, and during that period there occurred in all 39 deaths—viz. from tuberculous disease, 11; measles, 11; hydrocephalus, 4; convulsions, 4; whooping-cough, 3; fever, 2; diarrhoea, 1—Total, 39. A fraction more than one-third of the whole died of tuberculous disease, and one-half of these before the fifth year, the other half between the ninth and sixteenth—corroborating the opinion of Andral, who, from his extensive experience, remarks that tubercles

are most prevalent from the first to the fifth year; that they appear in much greater quantities, and in a greater number of organs at once: and that more than one-fourth of those who die from birth to puberty are affected with tuberculous disease. As the tendency of this disease appears to be the consequence of imperfect assimilation, there can be no doubt that we are possessed of the means of correcting this predisposition in many instances. Of this fact I have had abundant experience among the children of the Military Asylum. Few of the children, on joining this institution, were exempt on their admission from a tendency to tuberculous disease, which may reasonably be attributed to privations of different kinds, neglect, deficient nourishment, &c. &c. The great majority of the children, on their admission, and many for a long period afterwards, exhibited a strong tendency to struma, evidenced particularly by a disposition to a congestive state of the abdominal contents, impaired powers of digestion, depraved secretions, dry, harsh skin, and a tendency to eruptions, and ophthalmia (especially denominated strumous). Whilst under the ordinary circumstances of children of the same class, it has been calculated that five-sixths of those affected with tuberculous disease perish, it is a gratifying and a very important fact, that by placing children under circumstances the most favourable to health, as regards food, air, clothing, and exercise, the constitution becomes so improved as to overcome this predisposition, and, as we have seen, only fourteen cases of tuberculous disease proved fatal amongst 5,427 children of all ages.—*Dr. Hennen, in the Provincial Medical Journal*.

LITHOTOMY AND LITHOTRITY.

THE *Gazette Medicale* of November 19th contains an account of the operations for stone performed for some years past at the Hôtel Dieu, by M. Roux.

From 1836 to 1840, both inclusive, he performed lithotomy eighteen times; eleven patients were cured, and seven died.

He operated by lithotrixy in six cases. Three patients are said to have left the hospital, and three are reported to have left it cured.

Of these twenty-four patients, the ages were as follows:

From 3 to 25 years of age . . .	13
„ 25 to 50	3
„ 50 to 75	8

24

In the year 1841, seven patients suffering from stone were put under M. Roux's care. Six of these were operated on; four, namely,

by lithotomy, and two by lithotrity. The seventh patient was a little girl of 11, who had an enormous calculus; the very day of her admission into the hospital she sank under a diarrhoea, which had reduced her to the last stage of marasmus.

This year was the most fatal to calculous patients; for of six who underwent operations, five died: one of those on whom lithotomy was performed got well.

In one case, where a stone weighing 57 grammes, (1010 French grains) had been extracted by lithotomy, another weighing 62 grammes (1116 French grains,) was found on dissection; besides three of the size of a hazel nut, which were lodged in cysts.

In one of the lithotritized cases, it was found that a false passage had been made by grazing the tissue of the prostate with the *brise-pierre*.

TREATMENT OF MELANCHOLY.

EXERCISE, in whatever manner it is taken, is, without doubt, one of the greatest resources in combating melancholy; travelling, which acts on the brain by impressions, causing a crowd of images, and ever-new ideas, to pass before the understanding, necessarily destroys that fixedness of thought, that concentration of attention, which makes us lose all hope. Those patients who cannot travel must be exercised and diverted by excursions on foot, or in a carriage, by bodily exercises, by cultivating the ground, by the care of a garden, by household occupations, and by the practice of any profession. Riding on horseback excites the activity of the abdominal viscera, and favours insensible perspiration, while it lulls and diverts the attention. Good results are obtained from driving. The English struggle against the spleen by taking the place of their coachmen, and thus passing through the streets of London; the celebrated Alfieri rendered his dark melancholy supportable by this means alone. Sporting may fulfil the same object; but we must be cautious in trusting arms to those who are disposed to suicide. Pinel expresses the wish that every asylum for the insane should be near a farm, where the patients may cultivate the ground. Dr. Langermann had almost realized this wish at the Bareuth Asylum, where he was physician.

Dr. Horn has provided the insane patients in the hospital at Berlin with all the means of exercise compatible with their safety, and he derives great advantage from it. At the Salpêtrière, a considerable number of our insane women are occupied in sewing, knitting, and other manual work, and several are employed in the service of the house. These active occupations have their share in the

numerous cures obtained in this establishment. It is not so easy to furnish men with the instruments of work, because they may misuse them. Persons who have not been accustomed to employment, if it is impossible for them to travel, ride on horseback, or go in a carriage, should play at games which repose the mind and fatigue the body; such as battledore and shuttlecock, tennis, football, billiards, &c. But exercises of the mind must be joined to those of the body. Study contributes to cure the melancholic, provided it is not directed to subjects fitted to inflame the imagination. Sometimes, also, we give way to the melancholy ideas of him whom we wish to cure. M. Charpentier, in his excellent thesis on melancholy, relates that an ecclesiastic, who had become melancholic, with a propensity to suicide, in consequence of the revolution, was rescued from this state by the activity which he manifested in defending the Concordat, which was favourable to the independence of the ministers of religion.

A man was persuaded that his enemies had stripped him of all his fortune; i.e. became melancholy and morose, and refused to eat, because he had nothing with which to pay for his food: he was sent to Paris. After the lapse of some months, I advised one of his relations to feign a law-suit, and to persuade the patient to consult an advocate. The lawyer, previously instructed, asked for a written memoir, in order to be better acquainted with the state of the business. After some days' hesitation, the patient began a long memoir, which obliged him to go backwards and forwards several times, and even to undertake short journeys. A month had hardly passed, and the memoir was not finished, when it was clear that the disease was approaching a cure, which soon took place. M. Alibert relates a similar case. — Esquirol, *Des Maladies mentales: De la Lypémanie, ou Mélancholie*.

INSECT ORIGIN OF SMALL-POX.

By M. SERRES.

At the Institut, on the 4th of July, M. Serres mentioned the following fact, seeming to favour the hypothesis of animalcules in small-pox. By covering each pustule with a glass capsule, which is kept for some days in its place, he has seen the process of eruption either go on, or languish, or be completely abortive, according as the glass was transparent or more or less opaque. This influence was evidently due to the contact of the air. [Qy.—Should not this be the admission of light?] The experiment, he adds, was not merely curious, for it led to a modification of some of the hygienic mea-

sures adopted in small-pox. Previously, patients were generally placed in situations as well aired and lighted as possible; but now, one knows that dark situations are far better for this kind of disease, and that this change alone is enough to ensure the most favourable progress of its evolution. The success at La Pitié was never more complete than during one year when all the patients with small-pox had, of necessity, to be put into a low, ill-aired, dark ward—a sort of cellar. The confluent cases there went on as favourably as was possible. At present, in the same hospital, they are moved from the first floor into the *rez-de chaussée*, and they do well there.

M. Serres took this occasion to mention that he had seen between 1700 and 1800 cases of small-pox in private and in hospital practice, and that he was certain that the number of those affected with small-pox after vaccination was not greater than that of those who had small-pox twice. [For the first of these statements M. Serres may have made it probable, as our old physicians believed, that it is beneficial to exclude the light in small-pox; but there is no evidence that ill ventilation is to be desired.]—*Gazette Médicale*.

ON THE LOCAL EMPLOYMENT OF CALOMEL IN OPHTHALMIA NEONATORUM.

By M. LAUER.

THE introduction of finely-powdered calomel into the eye in ophthalmia was originally practised by Dupuytren. Professor Fricke of Hamburg has noticed, in his *Zeitschrift* for 1837, the violent reaction which its employment excites in the case of persons who have been taking iodine, probably owing to the formation of an iodide of mercury. About a year since Dr. Kluge began to use it as a local application in the cases of ophthalmia of new-born infants which came under his care in the lying-in department of the Charité at Berlin. The results were extremely fortunate, and Pr. v. Siebold of Göttingen, who was induced to try the remedy, has obtained from its employment very great success.

The manner of introducing the calomel into the eye is by means of a camel's hair pencil loaded with the powder, which is shaken from it into the eye, while an assistant separates the lids. In the treatment of the ophthalmia neonatorum this remedy may be had recourse to as soon as the first traces of the disease appear, and its employment once daily is then in general sufficient. After the lapse of from half an hour to two hours, according to the quantity of the secretion,

the eye may be washed from the powder, and the ordinary rules as to cleanliness be attended to. In severe cases the application may be repeated twice every day; but when the disease is mild a single application daily suffices to effect a cure in from four to ten days, if the remedy had been had recourse to from the outset. The more severe and intractable forms of the disease do not appear to have been benefited by the local employment of calomel.—*Medicinische Zeitung; and Brit. and For. Med. Review*.

FATTY AND CELLULAR DEGENERATION OF MUSCLE.

By DR. JOSEPH ENGEL.

ACCORDING to Gluge, the fatty degeneration of muscle consists in the deposition of fat, partly in a free, partly in an encysted state, between the primitive muscular fibres. The author is of opinion that the above is not the only metamorphosis which takes place, but is not able to persuade himself that an actual transformation of muscular into cellular tissue is to be admitted. So long as muscle, examined by the microscope, undergoes no other alteration than a mere change of colour, the form of the primary and secondary muscular bundles remains unaltered, except that their sheaths appear covered with a greater number of granulations, the greater part of which, however, are readily removed by a slight pressure. The sheath itself of the fibre appears more brittle and easily ruptured than before; the least pressure destroys its continuity. In the same proportion in which the fatty condition of the muscle and its loss of colour become apparent to the naked eye, do the longitudinal lines of the muscular bundles become more evident, the granulations more numerous, and the bundles themselves appear covered with a multitude of large bladders of fat, which, from becoming flattened, present various forms, and are at length united, partly with each other, partly with the bundles of muscular fibres, by a tolerably adhesive substance. The author failed to detect fat in a free state in fresh muscle; which, however, if treated with spirit of wine, gives out fat in notable quantity. Yet in this case the fat seems to be simply extracted from the sebaceous bladders or cysts by the action of the spirit of wine; these cysts, thus deprived of their contents, being visible, in a shrivelled state, between the bundles of muscular fibre. Water causes the fat to solidify, and to appear surrounding the muscular bundles like a sheath, from among which, by a slight pressure, it may be forced in the shape of half cylinders. The muscular bundles amid this deposition

of fat, partly free and partly encysted, lose entirely their sheaths; so that their delicate fibrillae (primitive fibres), after the fat being washed away, lie bare. This condition, and no other, it is which constitutes the so-called degeneration of muscle into fatty and cellular tissue, and which consists of nothing but a deposition of fat between the bundles of muscular fibres deprived of their sheaths. The sheath of the muscular bundles appears to be indispensable to elasticity, firmness, equal action, and vital function of muscle. Whether the change of colour which supervenes after some time in separated muscle be owing to the loss of the sheath, the author is not prepared to say. A question arises, whether the destruction of the sheath of the muscular bundles be owing to the deposition of fat, or whether the converse relation be the real one, or, finally, whether both changes be synchronous results of a common cause.—*Oesterreich. Medicinische Wochenschrift*; and *Brit. and For. Med. Review*.

APPARENT DEATH BY LIGHTNING.

By DR. HARTMANN, of Neu Ruppin.

THREE persons were at the same instant struck by lightning. In one the symptoms were severe and remarkable. He was a healthy man of twenty-six. When the author saw him, an hour and a half after the stroke, he lay completely unconscious, as if in apoplexy. His pulse was less than 60, full and hard; his respiration snoring; his pupils dilated and insensible. There were frequent twitchings of the arms and hands; the thumbs were flexed and immovable, and the jaws firmly clenched. Soon after the author arrived severe clonic spasms came on, so that four men could scarcely hold the patient in his bed; and his body was drawn to the left side. As soon as these had relaxed he was bled to 16 oz., cold was applied to the head, a blister to the nape, and mustard poultices to the legs. Stimulating enemata and opium were also administered; and in the course of twenty-four hours the patient's consciousness slowly returned, and he was soon completely recovered. The only external injury discernible was a red streak, as broad as a finger, which extended from the left temple over the neck and the sternum, to the precordial region, and which disappeared completely in a few days.—*Ibid*.

LITERARY NOTICE.

LECTURES
ON THE
PRINCIPLES AND CLASSIFICATION
OF DISEASE,

Delivered at St. Thomas's Hospital,

By THOMAS HODGKIN, M.D.

Lecturer on the Theory and Practice of Medicine
at St. Thomas's Hospital School.

At the conclusion of the preceding lecture a defined case of derangement affecting the hand was described to you, which served as an example of local disease—of the natural tendency to restoration brought about by what is called the *vis medicatrix naturæ*; and we have seen, that this local form may also lead to constitutional derangement, in which the disturbance of the system does not bear a direct relation to the functions of the part, as is the case when we have symptoms produced by interference with respiration or circulation. The symptoms of the constitutional disturbance might have been equally produced by the derangement of any other part. There are still many other considerations which claim our attention, without special reference to the function of the organ affected; we will therefore still keep to the case of disease in the hand. If we merely consider the variety of derangements of which this part may be the seat, we shall find that there are varieties in the phenomena which it is of great importance to attend to, depending upon the tissue composing the part to which the affection *particularly* belongs. Other variations are dependent on the causes of derangement, and others on the state of the person in whom they occur. It is to each of these in succession that I now invite your attention. The derangement may be merely on the surface, and affect the skin, and consequently be attended with considerable pain or uneasiness in consequence of the ample

supply of nerves; and even this uneasiness may vary in its character with the severity or depth of the derangement, so as to cause either burning or smarting pain, or the most annoying itching, a mere unpleasant tingling, or a great number of intermediate sensations, each, however, characteristic of the part affected. The kind of constitutional derangement, if it exist, will also be influenced by the tissue. Let us suppose the injury to be in the cellular membrane beneath the skin; this will probably lead to swelling and tension; a pain of a different kind will be felt; and it will frequently be accompanied by throbbing, perceptible to the patient and others in consequence of the resistance afforded to the arterial circulation. A greater degree of constitutional disturbance is likely to be produced than the extent of visible derangement might have led one to anticipate *à priori*; and frequently, even in the course of a few days, or even a shorter period, a new material, foreign to the part, and even to the system in a state of health, is often produced. This material, which is called pus, and is one of the most remarkable results of inflammation, is more particularly prone to be formed as a consequence of the derangement of cellular membrane. Its formation, in most parts, is accompanied by some peculiarities in the constitutional disturbance, of which rigors are perhaps the most remarkable.

The derangement may be yet more deeply seated; the sheaths of the numerous tendons entering into the composition of the hand, and the fluid which in health lubricates their internal surface, may become increased; the swelling produced by this cause, if simple, will not only be peculiar in its character and situation, but in the kind of uneasiness which attends it. It may have been produced slowly, and be accompanied with little or no pain; or it may have come on acutely, as in rheumatic affection, and be chiefly felt when any, even the slightest, attempt at motion is made; or it may have proceeded from injury,

by which the naturally close cavity formed by these sheaths has been opened. The symptoms dependent on such an injury, in the infliction of which scarcely any pain may have been experienced, may be of the most severe character, and prove rapidly fatal. I remember a case in which a tendinous sheath was carefully opened with a lancet, to allow the escape of the morbidly increased quantity of synovia, intermixed with numerous little loose bodies which had been formed in it. The operation, which at the time seemed very trivial, was as quickly followed by the most urgent symptoms: not only the whole hand became inflamed, but the constitutional derangement was so severe that the patient died in a few hours. Such serious consequences, in this and numerous similar cases, are referable to the particular tissue which becomes the seat of derangement; and we are consequently led to expect them whenever an extensive tendinous sheath, or the synovial capsule of a large joint, has been opened. But it may happen that the tendon enclosed in the sheath has suffered more than the sheath itself. This dense and feebly organised structure is but little sensitive to injuries which it may receive at the time of infliction, yet very severe pain may be felt where this structure has become inflamed. From its situation, however, we do not often see the affections of this structure in a simple uncomplicated form, which must be borne in mind in noticing both the local and constitutional disturbances which attend. There is one peculiarity to be noticed amongst the general disturbance which is apt to follow derangement seated in this structure. Though by no means exclusively, they seem, more than those of any other tissue, to lead to those formidable symptoms which we know by the name of tetanus—symptoms which, unlike those to which I have previously adverted as having a general character consequent upon the local affections which I have mentioned, and which have had more or less of a febrile character, principally marked by disturbance of the circulation, in some of its various forms, is, in the present instance, more especially connected with the mysterious functions of the nervous system. Tetanus resulting from such injury, will, therefore, doubtless, form one of the interesting topics upon which you will have the advantage of listening to my distinguished friend and colleague, Dr. Marshall Hall.

Again, the bones may be the seat of derangement. A different kind of pain will be felt; the progress of the disease will be marked by slow stages, and the appearance of the adjoining tissues, when they become affected in consequence of disease of the bone, will be peculiar and characteristic of the primary affection. Again, the derange-

ment may exist in the cartilage covering the ends of the bone, or in the synovial membrane associated with it.

The strongly marked differences in the symptom of disease dependent upon the particular tissue which it affects, has been strongly insisted upon by Pinel and Bichat, and thus lead to the important service which the latter has rendered to medical science in the list which he gave to general anatomy, which, before his labours, could scarcely be said to have formed a distinct branch of anatomy, although our countryman, Carmichael Smith, must be admitted to have preceded him in sketching its outlines.

Great as are the differences in the local, and also in the general symptoms, dependent on the particular tissue in which the derangement has its seat, there are likewise differences dependent on other circumstances equally worthy of attention, and which are to be referred to the nature of the existing derangement. In some of the instances to which I have already alluded, I have spoken of inflammation as taking place in the part. Inflammation is, indeed, one of the most common, and, upon the whole, one of the most important forms of derangement with which, in the practice of our art, we have to contend; but inflammation itself comprises several varieties; and there are likewise cases in which, though it may exist, there are other causes which give the more essential character to the case. Thus the inflammation may either be of an acute or chronic character; it may remain pretty much concentrated on a particular part, and, though intense, be little disposed to spread; or, on the other hand, it may have a different character, and be much disposed to advance from the spot at which it was originally seated—as we see in erysipelas, and those forms of inflammation which are allied to it. One of the consequences to which inflammation is apt to lead is the formation of an external wound or ulcer, and nothing can be more various than the appearances which these open wounds present—differences which it is of great importance to be well acquainted with, and readily to appreciate, both for diagnosis and treatment. In both of these respects, the details connected with them belong to the surgical division of your studies. They form, however, so essential a part of the general view, that they must not be passed over with mere allusion. Sometimes you will find the wound remaining day after day in *statu quo*, showing neither disposition to advance in the repairing process, nor to be attended with increase in the extent or severity of the derangement. It may be covered with a moist exudation of the part, but in other respects it might almost appear as if it existed in a part devoid of life. Such would be an extreme

case of indolence, both as respects the part and the system. When this is not the case, we may find, on the one hand, the repairing process advancing and characterised by the production of pus, the appearance of little red elevations upon the denuded surface, the daily increase of substance by which the wound is filled up, and its contracting margin formed by advancing new skin. Even in this state you may have varieties; the pus may not be all you could desire, and the new growth technically known by the name of granulations may be faulty both in colour and size. There are more modes in which, in the absence of the repairing process, the aggravation of disease may exhibit itself. The open wound may increase in size, its surface still presenting a fresh and ulcerating character. This is, perhaps, the commonest form of ulcers not disposed to heal; but there is a more remarkable and rapid form of such ulcers, to which the very appropriate name of phagedenic is applied. Sometimes the extension takes place by the manifest death rather than by the gradual and imperceptible erosion of the adjacent parts. In such a case the sore would be said to have a sloughing character. The occurrence of this manifest death, or sloughing, would conduct us to another form of derangement, which is rather to be spoken of as a sequel to inflammation. Without this consequence being produced, there are other varieties in the appearance and nature of the ulcerated part, or open wound, depending upon the particular cause which gave rise to it. Either at the time the skin was broken, or, in other words, the wound was produced, or at some subsequent period, some offending cause, possessing particular properties, may have been applied to the denuded surface. Some of these, like the bite of the adder and the sting of the scorpion, quickly produce a high degree of inflammation, accompanied with much pain and swelling, extending to a considerable distance from the point at which the injury was inflicted, and attended with a high degree of constitutional disturbance, which is rarely fatal, but continues for a few days. There are other poisons produced by animals of a similar description; but more especially by those of the ophidian or serpent class, the fatal energy of whose poisons is so great that death cuts off the sufferer before there has been any time allowed for the part to which the poison was applied to undergo those changes by which any great alteration in appearance can be effected. At the same time, it is extremely probable that in the minute structure of the part to which the poison has been applied changes do take place, which, if invisible to the naked eye, may hereafter be disclosed by microscopic research. There are animal poisons of another description which do not necessarily

belong to the animal producing them, but are the result of changes induced by disease; on which account they are called morbid poisons. Thus a human being or other animal, suffering severely from local disease and consequent general disturbance, may have some of his fluids brought into such a state that if an extremely small portion be taken from the living body, or very shortly after death, and introduced into a wound, the most intense and destructive inflammation may be set up, accompanied by severe and even fatal constitutional disturbance. Of this description are the injuries to which the members of our profession are exposed in pursuing practical anatomy, and more especially that department which is connected with the investigation of disease, because in such cases the bodies are nearest to that state in which death occurred. To most of you I trust that practical anatomy is sufficiently familiar; for the allusion which I have just made to the dangers which attend it produce no discouragement, and if you have experienced the effect which I have mentioned in your own persons, or witnessed it in those of your dissecting-room companions, you will not only understand the illustration which it affords, but appreciate those means which may be adopted to prevent the mischief or obviate its consequences. Some of these poisons lead to so much local injury in the vicinity of the spot to which they may be applied, as to produce local death, or sphacelus, to which I shall have occasion again to allude. As another instance of a morbid poison producing a peculiar character in the particular part to which it is applied, and thence affecting the entire system, I may adduce a very remarkable instance of the communication of a morbid poison from the teats of a cow to a chap or other abrasion in the hand of a milker. This will give rise to inflammation, producing a sore, which, in its elevation, surface, and character of the fluid which it contains, is recognisable as that specific pustule to which the name of cow-pock is given. More or less general disturbance of the system is produced in conjunction with it, but the wonderful consequence which ensues is, that the individual who has been so affected is not only exempt from the recurrence of the same affection, but in most cases from the influence of another most widely spreading and fatal morbid poison, that of small-pox. We must receive with thankfulness the blessing which the discovery of such a fact has proved. Our curiosity and desire to investigate may be excited to understand how such a marvellous result is brought about, but there is reason to believe that it must long remain amongst those mysteries connected with animal life which baffle the physiologist, and that in practice we must be content to

take advantage of it as a piece of well-directed empiricism. There are other morbid poisons more or less analogous to that of small-pox, which I need not particularize in this general review, as they will require to be spoken of in detail when we shall be engaged with the consideration of particular diseases, but for the sake of illustration I must mention two or three others of a somewhat different character.

In the instances of morbid poison of which I have already spoken, the constitutional affection has quickly followed the local application of the poison, and whether it has exhibited itself with great severity or comparative mildness, such derangement has assumed the character of an acute affection, terminating in recovery or death, in the course of a few days. In the case to which I have next to advert, the local application of the poison, though it may produce a sore, is not invariably followed by constitutional disturbance. When this, however, is produced, it supervenes at a much later period, and does not appear to have any tendency to spontaneous cure. By its affection of the system at one time, it affords no protection against the recurrence of the like disease from subsequent application of the poison. The morbid poison of which I am now speaking has another remarkable property, namely, that of being, when it has affected the system, *transmissible by descent* from the parent to the offspring, so that we may apply to it the proverb, "the fathers have eaten sour grapes, and the children's teeth are set on edge." This poison is that of syphilis, which for several centuries past has been the scourge of vice in civilized countries, by whom it has more recently been introduced amongst the ignorant and unsuspecting aborigines of uncivilized countries, where it has proved one of the most fearful of the exterminating agents which have been brought to bear upon the natives.

Although this poison is generally communicated through the medium of impure sexual intercourse, I am perfectly warranted in introducing it amongst the affections of that part of the body which I have selected as furnishing illustrations of the general view of disease which I am now offering. It has not very unfrequently happened that the surgeon or the nurse, in their attendance on a patient suffering from the influence of this poison, has received a portion of it on a cut or abrasion of the hand. The sore which has followed has assumed the peculiar appearance which characterises the syphilitic ulcer, and some of the numerous phenomena of constitutional derangement which it is capable of producing, have ensued.

It would seem that the unlimited period of time during which this poison may affect the system gives it an opportunity of com-

bining its influence with that of various other causes of deranged health, modifying the appearances which they present, prolonging their duration by annulling the tendency to spontaneous cure, and introducing the necessity for peculiar modes of treatment. Thus, many of the diseases of the skin are modified by syphilitic taint; the fauces, so liable to transmit inflammation from exposure to cold, become, under the influence of the same taint, subject to a most characteristic cyananche of longer duration; and if rheumatism attack the patient, to which the nature of his treatment may render him particularly liable, the symptoms of this affection are modified in their character, and in their treatment are found to be additionally intractable and obstinate.

LECTURES

ILLUSTRATIVE OF SOME IMPORTANT CIRCUMSTANCES CONNECTED WITH

OPERATIVE SURGERY,

Delivered at St. George's Hospital,

By SIR B. C. BRODIE, BART.

LECTURE I.—Dec. 7, 1842.

THERE is no department of the healing art in which there is so much to interest or to excite both our own profession and the public, as there is in operative surgery. In the greater number of cases of disease treated by other means, it is difficult to say how much of the success obtained belongs to the remedies employed, and how much to the natural powers of the patient's constitution. But it is entirely different in those cases that are the subjects of operations. Recourse is had to this mode of treatment only when nature can go no further; and an operation, so far from being the direction of a natural process to a safe result, is, for the most part, an abrupt and rude interference with whatever nature is about. If a cure arise from an operation, it is to be attributed to that, and to that only: and thus it happens that some of the most splendid results obtained in the healing art are those which are claimed by the operating surgeon.

But an operation, while it may do good, may also be productive of evil. A man has a stone in the bladder; he is suffering torture; he has nothing but a frightful death to which he can look forward. As the least of two evils, he is contented to submit to the operation of lithotomy; and, it may be, that in the brief space of three minutes he is placed in a situation of perfect comfort, and that in forty-eight hours you are able to declare with confidence that his life is perfectly safe. A man may have a disease in the knee-joint, with carious bone and abscesses; he may be worn out by pain, by perspirations, sleepless

nights, and other symptoms of hectic fever. You amputate the limb; and even on that very night he may sleep soundly; there may be no more perspirations, and in a week he may be gaining flesh, and present the aspect of health. But then, on the other hand, there are other cases, in which the patient, after lithotomy, may die within forty-eight hours, although he might have lived—in misery, it is true—had he been let alone, for a year or longer. So, in the case of amputation for a diseased knee-joint, the patient, instead of recovering, may die in the course of a few days, and very much sooner than he would have done had not an operation been resorted to.

This double result of operations adds to the interest which this part of surgery possesses, and to the responsibility which is entailed on those who practise it. But what adds still more both to the one and to the other, is this—that it is not only great operations, such as lithotomy, and the amputation of the thigh, that are attended with risk. A man died in this hospital from the consequences of the sting of a bee; and another died, in this hospital also, from those of the bite of a leech. A patient died in consequence of a wound, not an inch in length, on the inside of the knee, made for the purpose of dividing the saphena vein. I have known a patient die from erysipelas that followed the simple operation of cupping; and there have been not a few instances of fatal venous inflammation supervening after a common bleeding in the arm. A lady had a small encysted tumor on her head not larger than a pea. A surgeon who was at that time (for what I am speaking of was many years ago) an eminent man in his profession, removed the tumor, but did it imperfectly. The disease returned, and another surgeon, at that time in large practice also, removed it more effectually. The patient died from erysipelas of the scalp. So others have died from the removal of piles, and other apparently trifling operations.

Considering these different results that are obtained in operative surgery, you cannot but feel how essential it is that you should do every thing that can be done to make yourselves masters of whatever belongs to this part of your profession; that you should study the subject of each individual operation in its most minute circumstances; that you should be well acquainted with the anatomy of all the parts concerned in it; and that you should learn to be dexterous in the use of your knife, and of other instruments employed. You will also perceive that even these qualifications will not be in themselves sufficient. The surgeon who is engaged in operations must attend in all respects to his mode of life; and especially he should be of those moderate and temperate habits without which

there can be no steady hand, no accurate eye; without which, also, there cannot be that activity and energy of mind, and readiness of conduct, which are so necessary to enable him to meet the unforeseen difficulties that will continually arise in the greater, and sometimes even in the smaller operations, of surgery.

Some things to which you have to attend in an operation may be considered as special—belonging to that particular operation, and not to others. In operating for strangulated hernia, if you divide the stricture in one direction, you may wound the epigastric artery; while if you divide it in another, no such risk is incurred. In the operation of lithotomy, if you make your incision too extensive, you may cut through the whole of the prostate gland, and that is almost certain death to the patient. There are other things which belong to no operation in particular, but to operations generally, and it is to these last that I wish more particularly to direct your attention in the present lecture. You must not, however, lose sight either of the one or of the other if you would be accomplished operators.

An accomplished operator! That term may be used in various senses; but I will tell you, before I proceed further, in what sense I use it. I apply it, not to him who looks at his watch to see in how short a space of time an operation may be completed; nor to him who, during an operation, is putting himself in the situation of those who are looking on, considering what they will say, and anxious to appear dexterous in their eyes. According to my notions, he only is an accomplished operator who, before he engages in an operation, looks at all the consequences, both good and bad, which may ensue; and earnestly endeavours to lay his plans so that there may be as great a chance as possible of the former being obtained, and of the latter being avoided; and who, while actually engaged in an operation, thinks neither of himself nor of the bystanders, nor allows any question to arise in his mind except as to what he should do to bring the case ultimately to a safe termination with the least possible distress to the patient.

Let me exhort you never to slur over a single case, nor proceed to the smallest operation, without having well considered what accidents may happen, what evil may follow, what degree of danger may ensue; and, having done so, let me advise you further, that you should as far as you can, make the patient acquainted with all that you know upon the subject: or if he be not in a state in which he can judge for himself, then that you should make the same explanation to his friends. That you should do so is but an act of justice to your patient. It may be quite right for a man to run a risk by

going through an operation, but it is not right that he should do so without knowing it, or at any rate not without his friends knowing it. But it is also an act of justice to yourselves. A surgeon has no business to take all the responsibility of an operation upon himself. The friends should never have the opportunity of turning round upon him afterwards, and saying, "you said there was no danger, and here my wife, my husband, or my friend, is dead." In some of the greater operations, indeed, there is not much explanation of this kind necessary, because the world very well know that where you perform lithotomy or amputate the thigh there is a certain degree of hazard. But do not overlook the risk even of the smaller operations. If I am asked whether there be any danger, I never answer that there is none: I say, perhaps, what I have said to you just now, that I have known a person to die in consequence of the sting of a bee, and the bite of a leech; but then I add, that the danger is so small that it is not to be put in comparison with that which will arise from allowing a disease to remain, which is itself a source of danger: or if the disease requiring the operation be one of no serious character, then I may observe, that the patient must decide for himself, whether it be not worth his while to incur a very small risk for the sake of the relief which the removal of the disease will give him. We must all be contented to incur such risks as these in many of the common concerns of life. You may go out on horse-back, or on the top of a stage-coach, and may be thrown off and killed; you may be smashed on a railroad, or drowned when on board a steam-vessel. As these very trifling hazards are to be overlooked under other circumstances, so they are to be disregarded in the smaller operations of surgery. State all this to the patient, or his friends, in the way in which I have now stated it to yourselves. It will be a great comfort, and afford much peace of mind in the arduous profession in which you are engaged, if you attend to this advice. A man has a small tumor, and you remove it; the chance of mischief from the operation being not one in a thousand. But perhaps you are performing small operations daily, and to you, therefore, the chance is multiplied. It is almost nothing to the patient, but it becomes much to you; and it is especially for your own advantage that even these small fractions of danger should never be concealed.

There is no greater source of danger, you may well suppose, in operative surgery, than hæmorrhage. A large flow of blood may kill the patient instantly. If operators were careless on this point, there would be no want of examples of death from hæmorrhage: and even in spite of all the care that may be taken it happens sometimes

that patients die from loss of blood, either at the time of operation or very soon afterwards. When I was house-surgeon to this hospital, a patient had bleeding after lithotomy which could not be stopped, and he died in a few hours. I performed the same operation on a private patient, in whom there was hæmorrhage from the large veins, apparently in the neighbourhood of the neck of the bladder, which could not be stopped, and he also died in about a couple of hours. The danger from hæmorrhage is greatest in very early life. I have seen young children several times at the point of death from this cause. I accompanied an eminent surgeon, when I was young, to remove a nævus, or blood-vessel tumor from the back of a child's neck, (at that time nobody ever thought of removing those tumors except by the knife.) There was a good deal of bleeding at the time, but it appeared to have stopped. The child was put to bed, but in the course of a few minutes it was dead.

However, it certainly happens very rarely that patients die of hæmorrhage as an immediate result of an operation. Do not, however, think that hæmorrhage is of no consequence because it does not cause so frightful a catastrophe as this. The patient may survive a large hæmorrhage and be very well the next day, and the day after that, but it may lay the foundation of mischief, such as I shall describe in another lecture, which destroys the patient ultimately. Nor is this all. The patient may recover from the operation, and the wound may be healed, and yet, where there has been a copious hæmorrhage, the constitution of a delicate person, more especially of delicate woman, may be so much damaged by it, that it may not recover it for some years. After an operation I have sometimes heard a bystander say, "Oh, he has lost no more blood than it will do him good to lose." It is painful to me to hear such an observation as this: be assured that an operation cannot be performed with too little loss of blood. The loss of a few ounces in a patient who has a stone in the bladder, complicated with disease of the kidneys, will make all the difference between life and death: and so it is in many other cases. If it is desirable that the patient should lose blood, you can always take it from his arm, and just as is wanted, and no more. There can at any rate be no advantage from the loss of an uncertain quantity of blood in an operation. Some people seem to me to have a notion that the loss of blood in an operation will make the patient less liable to inflammation afterwards. But I believe that it is just the reverse. Bleeding may relieve phlegmonous inflammation where it already exists, but it does not prevent its existence; and on the other hand, I have no doubt that it increases the liability of the patient to other kinds of inflammation, such as

erysipelas, or diffuse inflammation of the cellular membrane, or venous and arterial inflammation. Those asthenic inflammations, if I may use the expression, occur especially in those persons who have lost much blood. Let it be your object, therefore, in every operation, that it should be performed in such a manner that there should be as little waste of blood as possible.

And I should mention to you that even a large loss of blood before an operation may be productive of the most disastrous consequences afterwards. A man had a lacerated wound of the thigh, his limb having been caught in some mechanical engine. There was considerable bleeding. He became faint, and the bleeding stopped. He was brought into the hospital in a state approaching to collapse. There was a great deal of injury, and it was evident that nothing could be done but to amputate the limb. The patient lay in bed waiting for what we call reaction to take place. By and by the pulse rose, and the wound began to bleed. The house-surgeon ran for a tourniquet, which unfortunately was not at hand, and before it could be procured the patient had lost an additional quantity of blood. We were then forced to wait till reaction took place a second time, and when it did so the limb was amputated. The patient was taken back to bed pretty well at first; all at once he felt an irresistible impulse to make water, but could not do it. A catheter was introduced, but the bladder was found empty. In a few minutes he died. On examining the body we found the heart flaccid and empty of blood: the vena cava superior and inferior, and the vena azygos, vessels which are generally full of blood, were all empty. The only blood that could be found was in the aorta and its larger branches. The heart had sent forth into the vessels the last drop of blood contained in it, but there was not a sufficient quantity of blood going the round of the circulation to fill the heart again.

To avoid an unnecessary loss of blood in operations, it is of course indispensable that you should have a thorough anatomical knowledge of the parts concerned; but you are not dependent on yourselves alone. Whatever may be your own skill, it will be insufficient, if you are not provided with a good assistant. It is sometimes better, when an operation is likely to be tedious, to take up the bleeding vessels as you go on; as, for example, in the dissection of some tumors, and even in some cases of amputation, where the patient has no blood to spare. Sometimes, where there is a long-continued dissection, you will find great advantage from using a silver knife with as sharp an edge as can be given to this metal. The silver knife will divide the cellular membrane and smaller vessels, but it will not divide any vessel of considerable size. As it divides the cellular membrane

it also stretches it, and elongates the vessels which are in it, and you know that vessels which are stretched before they are divided bleed but little.

It is a great mistake, (at least in my judgment,) to perform amputation without a tourniquet. I know, indeed, that you may stop the flow of blood in the femoral or in any other large artery, by the pressure of a strong man's thumb; but by means of a tourniquet you may prevent the bleeding from the small vessels as well as the large ones, and I need explain no further why it should not be neglected.

There is another point, which it is always worth your while to consider before an operation. Has the patient any particular disposition to hæmorrhage? There are some families in which almost every individual is liable to bleed in the most alarming manner from the slightest causes—in whom a pinch of the skin will cause an ecchymosis, and a wound with the point of a pen-knife will be followed by a serious hæmorrhage. Whether in these individuals the coats of the arteries are, as some have supposed, unusually thin, and incapable of contraction, or whether there be some peculiarity in the blood, so that it does not readily coagulate, I cannot say; but we know well the fact of the existence of persons who have this hæmorrhagic tendency, and in whom operations are therefore more than usually dangerous. A man came to this hospital, many years ago, with a wound in his forehead, and he nearly bled to death. The flow of blood was stopped at last, not by tying particular vessels, but by a general pressure; but it returned: it was again stopped in the same manner, but it again returned, and it was not till a large slough had been made by caustic that the hæmorrhage was finally arrested. This man, when younger, had had a bad tooth, and he went to a dentist to have it drawn, but he very nearly bled to death. Some time after he had been at the hospital with this wound in the forehead, he had another bad tooth. At first he was afraid to have it drawn, remembering the danger to which he had been exposed, but at last his toothache drove him to a dentist, by whom it was extracted. There was an abscess at the bottom of the tooth, which was in the upper jaw. A profuse hæmorrhage followed the operation. I was called in, two or three days afterwards, and he had been bleeding all the time. I tried various ways to plug the alveolus, and at last applied the cautery. It stopped the bleeding only for a short period, then it returned; and all other means having failed, I tied the carotid artery. This also was unsuccessful, and the bleeding went on, and ended fatally. This patient's child had the same hæmorrhagic tendency, and very nearly bled to death from the bite of a leech. There was a gentleman belong-

ing to a family of which I have seen many members, all of whom have this singular disposition to hæmorrhage. Upwards of twenty years ago, he sent for me to see him. He had symptoms of stone in the bladder, one of which was a most prodigious discharge of pure blood from that viscus. A surgeon whom he had consulted previously had declared him to have a *fungus hæmatode* of the bladder. I examined him, and found a stone. I recommended that he should go through the operation of lithotomy, but he said he should bleed to death; and a circumstance had occurred, since I first saw him, that seemed confirmatory of his opinion. He had been cupped in the perineum, and the wounds made by the scarificators had bled profusely every other day for nearly three weeks. Having seen a good deal of him, I partook of his fears, and was rather glad to avoid the operation. By and by he sent for another surgeon, who was in very large practice, and certainly had much more knowledge than I at that time possessed. He sounded him, found the stone, and said he had better be cut for it. "Oh!" said the patient, "I shall bleed to death." The surgeon, not being rightly informed on the subject, rather laughed at this: the operation was performed, frightful bleeding followed, which went on for twenty-four hours, and then the patient died.

There is another cause of fatal results at the time of, or immediately after, an operation; namely, the severe shock which, under certain circumstances, it may occasion to the nervous system. Sir Everard Home, in the instructive lectures which he formerly gave in this hospital, was accustomed to mention the case of a man who had a diseased testicle. He was placed on the table to go through the operation of castration. The removal of the testicle is a very simple process; there is no bleeding but what is under command, and there was no bleeding here: but when the testicle was removed, they looked at the man, and he was dead. When I was a student in this hospital, there was a man with a large stone in the bladder. Sir Everard Home, who was a dexterous lithotomist, performed the usual operation. The stone broke to pieces, and that at first seemed to be rather a good thing than otherwise, for it is better to take out a very large stone piecemeal, than to drag it out entire. But this occupied a long period of time, there being a deep perineum, and a great number of fragments. The operation I believe lasted a whole hour; then the man was taken back to the ward, but he was dead before he was in bed. This was probably nothing but the effect produced on the nervous system by a long, painful, and anxious operation, upon a healthy subject; and for such a contingency as this you cannot in all cases be

prepared. But you may be prepared for it in some cases by well considering the condition of the patient before you undertake the operation.

Suppose for example a man to have disease of the heart, with symptoms indicating ossification of the coronary arteries, that is, symptoms of angina pectoris: he will be much more likely to die from the shock of an operation than another patient; and therefore in him everything but the smallest operation should be avoided.

In the early part of my professional life, I was present at an operation of lithotomy performed on a patient who had many urgent symptoms of stone in the bladder: the urine was full of bloody mucus, offensive to the smell, and tinged with blood. The suffering which the disease occasioned was almost beyond imagination; but still it was a case in which, notwithstanding the greatness of the suffering, no surgeon with the knowledge we now possess would venture on an operation. This class of diseases was not so well understood at that time as it is at present; and two of the most distinguished surgeons of the day agreed in recommending lithotomy. The operation was performed; it did not last three minutes, and there was scarcely any hæmorrhage. The patient was taken off the table, but he was dead before he had been three minutes in bed. On examining the body, the prostate gland was found extensively ulcerated; and it seemed that the passing of the instruments over the ulcerated gland had produced that impression on the nervous system that proved thus instantly fatal. I witnessed another operation performed under exactly the same circumstances; except that there were several stones, and, therefore, that it was not so soon over. Before the patient was taken back to bed he was in a state of perfect coma, with stertorous breathing. In this condition he remained for some hours, and then died. A man was in the hospital with stone in the bladder, under the care of Mr. Ewbank: there was a consultation on the case, the question being whether the patient should undergo the operation or not. The symptoms were exactly similar to those which occurred in the two last-mentioned patients; and on the circumstances being stated to him, Mr. Ewbank at once gave up all thoughts of the operation. It was well that he did so; for on the following day the man died, and an extensive ulceration of the prostate, with disease of the bladder, was discovered on dissection.

Of course you may do a great deal towards preventing such a catastrophe by looking thoroughly into the case first, and it will indeed rarely happen that you may not anticipate and avoid the danger. Still, such a case may occur as that of a pa-

tient suffering in an unusual degree from the impression which the operation makes on his nervous system, and in which, by the proper and timely exhibition of stimulants, the system may be supported under it, and the patient's life preserved.

ON THE COMPOSITION OF THE BILE,

FOUNDED ON ITS ELEMENTARY ANALYSIS.

BY GEORGE KEMP, M.B.

Pet. Coll. Cantab.; Fellow of the Cambridge
Philosophical Society.

(For the *London Medical Gazette*.)

THERE is not, perhaps, in the whole range of physical science, a subject which has afforded more ground for diligent research and hypothetical deduction, than the biliary secretion. To the chemical philosopher the difficulty of the investigation, and the contradictory conclusions of the most upright and intelligent observers, urge him to renew the attempt to reconcile the discrepancies: to the physician, the daily observation of phenomena which could only be traced to an altered state of a secretion, the very nature of which was involved in obscurity, furnish him with motive enough to avail himself of the slender assistance which physiology afforded him to arrive at something like general deductions on the subject: while the very charlatan, safely sheltered under the obscurity of "bilious affections," has never been backward to make use of them for the advancement of his own interest.

The utter hopelessness of arriving at any satisfactory conclusions from the examination of the bile by means of reagents, must be considered as placed beyond a doubt, by the acknowledged fact, that a large portion of the substances obtained in the usual analysis of the bile are products of decomposition brought about by the reagents themselves; and this consideration induced Professor Liebig to suggest the necessity of an appeal to elementary analysis as the only legitimate means of eliciting general truths, and affording the physiologist and pathologist something like fixed views on this

interesting and important subject. The writer cheerfully undertook the investigation; and if the facts of the case compel him to differ in opinion from those whose probity and love of truth have endeared them to men of science, as much as their deep research and extended labours have rendered them illustrious, he is convinced that they will be the last to reflect on the incompleteness of the research on a subject involved in so much obscurity, and embracing so wide a field.

As a preliminary observation, it may be remarked, that the main object kept in view in the following research was to eliminate the body which presented the most constant and characteristic ingredient in the bile; and to arrive at this object two things seemed desirable:—First, to prepare the subject of analysis from bile obtained at different times, under different circumstances, and subject to different methods of preparation; and secondly, to submit the same portion of bile to different modes of treatment. The most sceptical or scrupulous could hardly suggest a more rigorous or severe control; whilst, on the other hand, a less rigid mode of demonstration ought to be rejected as unsatisfactory, because defective. It was, at the same time, conceived, that should a body present itself under the above circumstances, which possessed constant identical or even strictly analogous physical and chemical characters, no sound judgment could be justified in rejecting the evidence afforded of its being a simple body, in the usual acceptation of the term. A compound substance may, indeed, exist, in which a variety of bodies may enter, but in that case, to insure constant chemical composition; and uniform physical characters, these bodies must coexist in constant, unvarying proportions; and even supposing the bile to be such a substance, it must, in a practical sense, be treated as a simple body. In the sequel, however, we shall find reasons for concluding that the view of Demareçay is correct, and that the bile consists essentially of an electro-negative body in combination with soda. And having alluded to Demareçay, it would not be ingenuous to conceal the fact, that no researches founded on the reaction of other bodies can be placed in comparison with those which admit of no hypothetical deductions, but rest

exclusively on demonstrative evidence for their establishment; and it is singular that the only defective point in the investigations of Demargay, was the remaining content with the analysis of the acid obtained from the action of hydrochloric acid on the bile, and then resorting to probable evidence in order to establish the identity of choleic acid and the electro-negative body, which, in combination with soda, forms the principal ingredient in the solid portion of the bile. It is true, that the quantity of soda in this fluid was ascertained by direct experiment, and found, as nearly as possible, to equal the quantity of soda which combines with choleic acid; the soda, however, was estimated as sulphate, which precluded the possibility of ascertaining the quantity of chloride of sodium always present and in varying proportions. The following review of the well-known analyses of Berzelius and Thénard will show how easily the above mode of determination may lead to false conclusions.

Berzelius found of chloride of sodium, lactate of soda, and extractive matter, 0.74 per cent.; this would represent at least 0.40 per cent. of soda, not calculating the quantity of this base combined with phosphoric acid. Thénard found chloride of sodium 0.40 per cent., phosphate of soda 0.25 per cent., and sulphate of soda 0.10 per cent. These quantities represent at least 0.3 per cent. of soda. In either case, a serious error in the atomic weight would result in the second figure. For the convenience of the reader, the different substances submitted to elementary analysis in the following research will be referred to different portions, with the description of the mode of preparation, physical characters, &c. preceding each series of analysis. I must here acknowledge myself indebted to Dr. Heiligenhöfer, of Frankfort, for his politeness, on two occasions, in obtaining for me the bile of a large number of oxen killed at the same time, and immediately evaporated to a thick extract in a water bath. The first portion consisted of the bile of twelve oxen, and was that used for the experiments and analyses described under the head Portion I. The second quantity of bile, from an equal number of oxen, was devoted to the investigations included under Portions II., III., and IV. Thus it will be seen, that every effort

was made to arrive at accurate average results, and, in fact, these were more uniform than the writer expected.

PORTION I.—The bile, received in the form of extract, was treated with alcohol, sp. gr. 850, in order to remove the mucus, the whole filtered through linen, and subsequently through paper; the clear solution evaporated *in vacuo* over sulphuric acid; the resinous mass thus obtained reduced to powder, and treated with ether free from alcohol and water. If the ether is not deprived of these bodies, the powdered matter cakes together, and thus a very small surface only is exposed to its action (See Berzelius, *Annalen*, B. 43, H. 1); the ether was poured off, and another quantity added; the process being continued until, on evaporation, no residue was perceived; the residue again dried under the receiver, and treated with alcohol, sp. gr. 840, filtered, the clear solution evaporated *in vacuo*, and reduced to powder for analysis. On reviewing the above mode of preparation, it will be remarked that no reagent had been used which could be presumed to effect any decomposition or metamorphosis; the use of barytes, sulphuric acid, oxide of lead, &c., was entirely excluded; and thus it was hoped that the body obtained expressed at least the *sum* of the elements composing the essential ingredient or ingredients of the bile. The only objection that could arise was the possible presence of fat acids in combination with soda; and it must be confessed that this circumstance presented such difficulties in the analyses, that subsequently a different mode of preparation was resorted to. The salts of the fat acids were ultimately removed, but not until a very large quantity of ether had been used, as will be seen by the following considerations. Of the neutral stearate of soda not more than 0.15 per cent. is soluble in ether; of the margarate of soda 0.17 per cent., and of the oleate of soda, which is much more soluble than either of the above, only 1.14 per cent. (Berzelius, B. vi. section 532, &c.) Thus it appears that of the most soluble of these salts 99 parts in weight of ether would be necessary; and of the least soluble, nearly seven hundred, to insure their removal. In the above experiments, however, a much larger quantity was used before the ether left

no residue on evaporation. The result of the analysis of the substance, when perfectly freed from fat acids, was as follows:—

0·253 grammes gave Carbonic Acid = ·538 ∴ Carbon = 58·46 per cent.

Water = ·190 ∴ Hydrogen = 8·30

The object of the analysis in the present stage was merely to make a general comparison of the constitution of the substances obtained by different modes of preparation; the quantity of inorganic matter, therefore, has not been deducted. We now pass on to—

PORTION II.—The bile was deprived of mucus as above, the clear solution precipitated with barytes water in slight excess, and filtered; the filtered solution treated with carbonic acid to remove the excess of barytes, again filtered, and the clear solution mixed with one-third its bulk of ether, well agitated, and treated with distilled water until it became opaque. This mode of separating the fat, &c. is preferred by Professor Liebig, and is an important improvement, as it is not necessary afterwards to waste a large quantity of water-free ether. On setting the solution aside it soon separated into two layers,

0·300 grammes gave Carbonic Acid = 0·638 ∴ Carbon = 58·46 per cent.

Water = 0·238 ∴ Hydrogen = 8·81

The inorganic matter in the two above portions was carbonate of soda, with a small quantity of chloride of sodium; and the results seemed strongly to confirm the opinion of Demarcay, that the bile is an inorganic acid in combination with soda. It now seemed probable that by carefully removing the inorganic bases in the form of sulphates, and the fat acids by means of ether, we should be able to eliminate the body sought for in an isolated form, or at least to produce the salt of soda artificially. The latter plan was adopted as least difficult, and presenting fewer risks of a mixed result. The method pursued was as follows:—

PORTION III.—The bile was deprived of mucus as above, and filtered; the clear solution precipitated with barytes water, and again filtered; the resulting clear solution treated with a slight excess of sulphuric acid, diluted

0·244 grammes gave Carbonic Acid = ·523 ∴ Carbon = 58·8 per cent.

Water = ·187 ∴ Hydrogen = 8·51

Or, putting the results of the above together,

	I.	II.	III.
Carbon =	58·46	58·46	58·8
Hydrogen =	8·30	8·81	8·51

the upper etherous portion containing the uncombined fats, &c. and the lower containing the substance intended for analysis. This portion was separated, evaporated, and dried in an oil bath, at 110° Celsius, powdered, and treated with ether until it left no residue on evaporation. The remainder of the process was similar to the foregoing in Portion I.

The physical characters of this body were perfectly similar to those of the former portion: it is unnecessary to repeat them, as every person likely to read this paper is acquainted with the characters of bile reduced to an extract. One important point, however, must be borne in mind, that neither this nor the preparation Portion I., was precipitated from its aqueous solution by acetic acid. The following were the analytical results:—

with five times its weight of water, and filtered. It will thus be seen that the bases were precipitated in combination with sulphuric acid. To remove the fat acids the clear solution was treated with ether, and separated as above. It was now saturated with carbonate of soda, and the sulphate found precipitated in the alcoholic solution. The carbonate of soda was used in excess, and agitated in the solution repeatedly. If, now, an electro-negative body remained in solution, which had a greater affinity for soda than carbonic acid possessed for that base, it was evident that it would combine with it. On filtering, evaporating, drying in an oil bath, &c., a body was obtained possessing precisely the same physical characters as the preparations obtained from I. and II. and not precipitated by acetic acid. The following results were obtained by analyses:—

Such a resemblance in three analyses obtained from a substance prepared under totally different circumstances, hardly leaves a doubt that we were operating on the same substance. The

new method of Drs. Varrentrapp and Will. A vast number of similar cases could be given, but this is unnecessary, as Dr. Will is just about furnishing the public with the results of some decisive experiments, which will set the matter at rest for ever.

As the present investigation is merely the commencement of a series of researches into the elementary composition of the bile, we have not ventured to propose a formula; indeed, it is evident that, with the imperfect knowledge which we as yet possess on the subject, such an attempt must be considered as a mere hypothesis, or probable inference, which the very next analysis might overthrow. We think, however, that the facts elicited justify the following conclusions:—

1. That the bile of the ox is a *chemical compound* of an electro-negative body with soda.

2. That this body is not the *choleic acid* of Demarçay, as it is not precipitated from its combination with soda by acetic acid.

3. That it is not the *bilin* of Berzelius, as it is not separated from soda by means of carbonic acid. Repeated experiments were made on this subject under circumstances peculiarly favourable to the separation of the soda in the form of carbonate. The compound forming the subject of the last analysis was dried in an oil-bath at 110°, and then dissolved in alcohol, sp. gr. .809, at 15° C.; a very strong current of carbonic acid gas was now passed through the solution for two hours. No precipitate took place. Another experiment was made with bile taken out of an ox immediately after it was slaughtered, and while the secretion was warm. The mucus was separated with alcohol, and the clear solution evaporated to dryness. It was now again dissolved in alcohol, sp. gr. .809, filtered, and exposed to the action of carbonic acid gas as above. This experiment also proves that, in this case at least, no *free* soda was contained in the bile.

With reference to the peculiar sweetish taste of the bile, the opinion has been advanced by Berzelius that it may probably arise from the free *glycerin* held in solution. If this were really the case, on subjecting the bile to destructive distillation we ought to perceive a distinct smell of *acrolein*.

In no case have I obtained this result, although, in the above investigations, fifteen general determinations of ash were made; and in the course of these operations the peculiarly pungent nauseous smell of *acrolein* must have been developed had any glycerin existed.

Such are the most important of the results which the writer has obtained from upwards of seven months' researches, and more than forty analyses. The object has been to support no theory, and, as much as possible, to avoid the prepossessions which a diligent study of the previous researches of others was calculated to produce.

For the deficiencies, he feels that every allowance will be made by the only competent judges on the subject—those who have been themselves engaged in the difficult department of animal chemistry. A wide field yet remains open in the ultimate analysis of the human bile, the bile of fishes, and a general comparison of the bile of graminivorous and carnivorous* animals. The writer proposes to devote himself to the investigation; and hopes that, if ever completed, much of the obscurity which at present envelops the subject may be removed, and some general facts established directly applicable to the treatment of an important class of diseases.

Giessen, Nov. 21st, 1842.

THE SURGICAL TREATMENT OF IMPAIRED VISION,

CONSEQUENT ON THE OPERATION FOR STRABISMUS; ILLUSTRATED BY A CASE.

To the Editor of the Medical Gazette.

SIR,

IF the accompanying case, which is intended as an illustration of the treatment of one of the ill consequences which occasionally result from the operation for strabismus, be thought by you worthy of the pages of your valuable

* The examination of the elementary composition of the bile of the strictly carnivorous animals was undertaken by me, at the request of Professor Liebig, in the month of May last. A fox was the animal from which the secretion was obtained; but the quantity was so small that no general fact can be deduced from the analysis, as there was not enough for nitrogen analysis or control. I trust shortly to be able to obtain in England the bile of the lion or tiger, as the type of the carnivorous animals.

ble journal, its early insertion will much oblige,

Your obedient servant,
JAMES J. ADAMS.

27, New Broad Street, Dec. 1, 1842.

Of all the ill consequences which have occurred after the removal of a squint by the section of one of the recti muscles, no one has produced so much alarm to the patient, anxiety to the surgeon, and injury to the reputation of the operation for strabismus, as the impairment of the vision, either in the eye operated on, in its fellow, or simultaneously in both; for, as yet, in many instances where the sight has been impaired by the straightening of a squinting eye, medical treatment has failed to afford relief.

Having witnessed, in several cases of the kind above mentioned, the difficulty and failure of medicine to relieve the impairment of the vision, I directed my attention to the peculiarities of the defective sight, and found them to be such as to lead me to believe that an undue contraction of certain recti muscles of the eyes might induce that kind of impaired vision which succeeds to the straightening of an eye after the division of its contracted muscle; and therefore, that a surgical mode of treatment might be employed. The following case is an instance of the successful application of a surgical treatment.

Aug. 9, 1841.—Ann Clancy, æt. 22, and healthy, applied to me for relief to her sight, which she described as being so defective, as to render her incapable of earning her living by any occupation requiring ordinary exertion of her eyes. The positions of her eyes generally were natural, but occasionally not so when viewing attentively near or distant objects. On examining the power of her sight, I ascertained that she could not see to read letters of small print, nor to thread the eye of a common-sized needle; and that large sized letters, which she could distinguish at first sight, could not be recognized after a gaze on them for five minutes; also, that the longest time she could continue to exert her eyes over letters of large size did not exceed twenty minutes, though aided by frequent rests; for the sight then became so dim as to require a rest of the eyes during the space of many hours before she again could distinguish the form of

a letter: therefore, her sight was defective as to clearness and power of continued exertion.

If the right eye was used by itself, its sight was as defective of clearness as that of both, but its disposition to an increasing dimness, during exertion of the eyes, much stronger.

The sight of the left eye, used separately, was more defective in clearness than that of the right, and its dimness less disposed to increase, during exertion, than that of the sight of both eyes.

The dimness of her vision was accompanied by severe pain across the forehead and left brow.

History.—At the age of two years she squinted strongly with the left eye in the direction of her nose. As she grew older, the squint lessened; and it was then observed that, in proportion to the gradual straightening of the eye, the sight of it became impaired. In December 1840 the squint of her left eye was slight, and its sight very defective, though the sight of both eyes, and that of the right, when used by itself, was perfectly natural as to clearness and strength, so that the defective sight of the left eye did not produce any inconvenience to her. However, she felt anxious to have her eye straightened, and for that purpose applied to an eye hospital, and placed herself under one of the surgeons, who divided the internal rectus muscle of the left eye, the position of which instantly became divergent, and its sight, with that of the right, confused and double. The subsequent effects of the wound of the operation were large troublesome granulations, and severe prolonged irritation of the conjunctivæ scleroticæ. During the succeeding months, January and February, the same state of confused and double vision, with some additional sense of weakness, existed, though she had not attempted to read or work. In March she first attempted to use the eyes in her ordinary occupation, and ascertained the degree of the defect of her sight, which, as to clearness and power of continued exertion, she believes to have been at about half of its present degree. From March to the succeeding August her sight declined in clearness and strength, notwithstanding many occasional and remarkable variations in its degrees of imperfection:

e. g. sometimes during a few minutes it would be perfectly restored to her, then suddenly be rendered darker, nearly to complete blindness, in which state it would remain for a few minutes, and then return to its usual condition : at other times it would remain improved during several days, and then, for an equally brief period, be more than usually impaired.

The treatment of these symptoms of amaurosis was conducted, by the surgeon who removed her squint, steadily and with much attention, during a period of nine months; and the means he employed were those usually adopted in obstinate cases of amaurosis, namely, purgatives, alteratives, mercurials, tonics, counter-irritants, &c. However, the result of his treatment being unsuccessful, he told her "that he knew not what more to do for her;" soon after which she applied to me. Having had the opportunity of witnessing her medical treatment, which had not been wanting in skill, I determined not to repeat it, but at once to apply a surgical treatment I had previously adopted with success in cases where the vision was impaired, and the position of the eyes natural.

On August 9th I divided the internal rectus muscle of the right eye; the effect of which was an immediate divergence of both eyes, particularly of the right.

17th.—Both the eyes much diverged, but the left more than the right. Sight of the right eye improved in clearness and power of continued exertion; that of the left not improved. Double vision not so distinct as before operation.

24th.—Divergence of the eyes single and alternate. Sight improved, *e. g.* can see to read newspaper print during the space of two hours, without any dimness of the sight occurring to need a rest of the eyes. By the left eye alone can see to read type "great primer." The pain of the head and eyes has not been felt since the second day after the operation.

September 4th.—Position of the eyes nearly natural, but subject to alternate divergence. Sight much improved, *e. g.* she can see to read "pearl" type from the distance of eighteen inches, and to read or work with her needle during three hours at a time. Double vision still present.

6th.—Divided the external rectus of the left eye.

12th.—Position of the left eye central; that of the right slightly divergent. Sight not quite so perfect as it was previously to the last operation; the vision of the left eye has not improved, and that of the right is less perfect.

21st.—Sight, with both eyes open, remarkably improved; she states that it is now as perfect "as she has ever known it to be," for she can see to read, or to do fine needlework, during as many hours as she may please, without feeling the least degree of inconvenience from dimness of the sight or aching of the eyes. By the left eye she can read type "English." Double vision is yet present.

27th.—Divided the external rectus of the right eye (without removing a portion); and the immediate results were, an apparent central and correspondent position of both eyes, and a lessening of the double vision.

29th.—The sight remains unaffected as to clearness and power of continued exertion. The double vision has not ceased, but much lessened.

October 22d.—Position of the eyes variable; sometimes central, at others subject to a slight alternate divergence. Sight of the left eye improved; can see to read "pearl type" by it.

November 25th.—Position of the eyes generally natural, but occasionally not so, either the left or right eye being slightly divergent, while its fellow is central. The sight continues to be perfect as to clearness and power of enduring lengthy exertion; for on no occasion has any return of its late defective symptoms been produced. The sight of the left eye has ceased to become dim after exertion.

January 1842.—The position of the eyes and state of the sight are nearly the same as when last reported, the only exception being, that the twofold appearance of objects is more troublesome to her from its being distinct in proportion to the intentness with which the object is viewed.

31st.—Redivided the external rectus of the right eye, the immediate effects of which were a central position of the right eye, with a convergence of the left and a lessening, with alterations, of the double vision.

Feb. 10th.—Position of both eyes perfectly natural; double vision less

distinct, and not so frequently seen; sight, in other respects, natural.

April 25th.—Appearances of the eyes natural, and their position perfectly so to any but a very accurate observer; for the slight variations in their consensual movements can only be detected when she is directed to look suddenly and attentively to different distances.

Oct. 6th.—Prominence and position of her eyes quite natural; the power of convergence slight, and equal at four and a quarter inches. The power of inverting the right cornea is complete; that of the left is not so by one and a half lines; the power of eversion is not complete in the right eye by one line, nor in the left by one and a half lines.

Sight natural in its clearness and power of continued exertion, with both eyes open, or by the right eye alone; *e. g.*, she can see to read the finest engraved letters, namely, those which express the Lord's prayer within a circle of less size than that of a four-penny-piece. If the left eye alone be used, such small letters can only be distinguished separately, so that she spells, instead of reading, the words by it.

The above case having been related particularly with the view of illustrating the effects of the division of the recti muscles on the sight, I have intentionally omitted many interesting facts with regard to the positions and motions of the eyes.

REMARKS.—In order that the facts of this interesting case may be the more strongly impressed on the memory of the reader, permit me to add a brief review of them.

In December 1840, A. C., 22 years of age, submitted to the operation of division of the left internal rectus muscle for the removal of a convergent squint of the left eye. The results of the operation were a complete straightening of the eye operated on, and a defect of the vision of both eyes, characterised by a want of clearness, strength, and singleness. During the nine months succeeding to that of the operation, the position of both eyes maintained a nearly natural correspondence in a central direction, but the sight, during the same period, became more and more impaired, although medical treatment was constantly and skilfully applied. On August 9th, 1841, the position of her eyes

being nearly natural, and her sight so defective in clearness and power of continued exertion, as to render her incapable of earning her living, the internal rectus muscle of her right eye was divided. In the course of a few days after the operation an extensive improvement of the sight took place. On September 6th, the external rectus of the left eye was divided, and on the 24th instant, her sight, when both eyes were open, had become, according to her own statement, as perfect as she had ever known it to be in respect to clearness and strength; but not as to its singleness. September 27th.—The external rectus of the right was divided, and a further improvement to the vision, particularly to that of the left eye, succeeded the operation.

January 1842.—Sight naturally clear and strong, but yet subject to a state of double vision.

31st.—The external rectus of the right eye redivided, by which operation the positions of the eyes were rendered more natural under every circumstance, and the double vision nearly removed.

October.—The sight of both eyes equal and perfectly natural.

ON THE
CONSTRUCTION AND APPLICATION
OF
INSTRUMENTS USED IN AUSCULTATION :

Being the Substance of a Communication made to the Medical Section of the British Association at Manchester, in June 1842,

By C. J. B. WILLIAMS, M.D. F.R.S. &c.

THE acoustic examination of disease having been so profoundly as well as generally studied, it is not surprising that the instruments used in it should have wanted modifications to make them exhibit better the phenomena which increased experience and skill have discovered. To make these improvements some knowledge of acoustic science is necessary; and it might seem to be the province more of the natural philosopher, than of the physician, to suggest them.

But it must be borne in mind, that a good understanding of the ends in view, as well as of the instrument, is required. To suggest what a stetho-

scope ought to be, a knowledge of acoustics is not more necessary than an acquaintance with disease, and experience in its investigation. A want of these latter qualifications, in my opinion, renders some recent suggestions from the Professor of Natural Philosophy at Edinburgh*, of little value to practical men; and an imperfect acquaintance with the whole of the purposes and principles of the stethoscope seems to me apparent in other late proposals for the improvement of the stethoscope.

Twenty years' attention to the principles and practice of auscultation may perhaps warrant me in offering to the section a few remarks on the acoustic principles of means used in auscultation, and on the best mode of applying them with efficacy and convenience.

Laennec, the inventor of the stethoscope, had no accurate views of the principles of its construction. He declared that the instruments which he found the best, were not made according to the commonly received laws of physics. Yet experience taught him that the solid cylinder does not convey breath sounds, or voice sounds, so well as the cylinder perforated and hollowed at its pectoral end. Many years ago I pointed out that this fact, which is unquestionable, is in perfect conformity with a law of acoustics, that sounds are best conducted by bodies of an elastic tension resembling that of the sonorous body. On the other hand, bodies differing in elasticity are bad recipients of each other's vibrations. Thus wood, although an excellent conductor of sounds generated in itself, or in other solids, receives but imperfectly those produced in air. But by thinning wood, and extending its surface in contact with air, it is much more readily affected by the vibrations of air, and becomes the best medium for transferring to air the sounds of denser solids; and this is the principle of sounding-boards.

The view which I originally gave of the principle of the stethoscope represented its operation as varying with the source of sound: sounds produced in air (vocal and breath-sounds) being best transmitted by an enclosed column of air; those produced in solids (rhon-

chi, heart, and friction sounds) being most effectually communicated by rigid solids of the least density. This view I still hold; and I proceed to remark on the best mode in which the principle may be brought into operation.

It has been lately questioned that the conducting power of the stethoscope depends at all on the air contained in the central canal and excavation. This doubt has arisen chiefly from an observation first made by Dr. Cowan, that plugging the central canal does not much impair the power of the instrument. Professor Forbes has repeated the same remark. I have made many experiments on this point, and the following are some of the results.

Stopping with a cork the pectoral end of the instrument greatly impairs its conducting power; stopping the ear end does so in a much slighter degree. But in any way stopping the tube does impair the transmission of sound; and to be assured of this, it is not sufficient to judge by general impressions as to whether a sound is louder in one way than in another: we must resort to what may be called a *test sound* (as opticians use a test object); a sound just within the limits of audibility, such as the sound of expiration in a healthy subject, or a very faint cardiac murmur. When tried by such a test, the superior conducting power of the open tube becomes obvious. But the impeding effect of a stoppage in the tube becomes most evident in the flexible stethoscope, a cork inserted into the pectoral end of which altogether shuts out faint sounds, and very perceptibly impairs those that are louder.

That the common stethoscope really conducts by its closed column of air as well as by its solid walls, is further proved by the following facts. Loud pectoral sounds, as that of the voice, heart, or a murmur, may be heard by bringing the ear end near the ear, without actual contact: the sound is then exclusively conveyed by the air, and may be totally intercepted by a plug. If a large hole be made in the side of a stethoscope, its conducting power is greatly impaired, especially for areal sounds; but it is at once restored by closing the hole with the finger. The difference depends not only on the exclusion of extraneous sounds by the

* Edin. Monthly Journal of Medical Science, July 1841.

latter expedient, but also, and chiefly, on the superior power of conduction which a closed column of air possesses. That the addition of solid conductor, by that which stops the hole, is not concerned in the improvement, is clear from the fact, that solid tubes of the most slender walls avail as well as thick ones, so long as they preserve a close column of air within them.

The closed state of the column of air is the chief condition necessary to give air a high conducting power. Following the assertions of acoustic writers, that the pulses of sound pass through the air in straight lines, like rays of light, I formerly suggested that the pectoral end of the stethoscope should be hollowed into a very tapering cone, and that the whole interior should be made as smooth as possible, to promote the most direct reflection of sound. But this principle is more applicable to ear trumpets, which receive sounds from the open air, than to the stethoscope, which receives vibrations from a solid enclosed surface. Air confined in a close tube vibrates as a whole, and its vibrations pass over angles, and through bends (as in a flexible tube), with a freedom which supersedes the idea of mere reflection; and although they must be transferred through a straight smooth tube more freely than through a crooked and rugged one, the difference is less than might be expected without a knowledge of the properties of close tubes.

The chief object in the formation of the hollow end of the instrument is to bring into close contact with the walls of the chest as large a surface of air as possible, and to convey the pulses of this air as directly as possible to the ear. It is at the same time desirable to avoid a large hollow within the instrument; because such a hollow causes a conch-like or tinkling echo, from the repeated transverse reflection of the vibrations. A conical cavity answers very well for the sounds best transmitted by the air; but a trumpet end does not appear to be inferior, and it answers better for the communication of vibrations to the solid part of the instrument.

I have before noticed the inferior power of a solid stethoscope. Some writers, who consider the stethoscope to conduct only by its solid walls, ascribe this inferiority to the weight of

its mass, and suggest that if this be reduced by hollowing, the closed solid is still the best instrument. To test this principle I had a thin stethoscope made of light deal, and closed at its pectoral end by a very thin plate of the same material: this proved to be decidedly inferior to instruments with an open bore*. Yet this instrument reversed, with its closed end applied to the ear, and its open end on the chest, communicated all diffused sounds uncommonly well: this can be explained only on the principle of the large surface of the hollow of the instrument enabling the solid part to receive the vibrations.

But finding the considerable share which the solid walls of stethoscopes have in communicating sounds, and finding by experiment that their efficacy depends chiefly on the formation of their pectoral end, by which they receive the vibrations, I have devised a form of instrument which qualifies them for this purpose better than any instrument now in use. It is the bugle or trumpet end (as seen in fig. 1, A),

the edges of which being made very thin, and applied flat on the walls of the chest, are most readily affected by their vibrations. The instrument thus constructed, of a light rigid wood, such as sycamore, if tried with a test sound, will be found for most purposes superior to the stethoscopes hitherto used.

* The same inferiority is manifest in a light solid instrument, which I have seen used by one or two practitioners.

But most stethoscopes are provided with a perforated stopper, the chief use of which is to shut out diffused sounds, and to transmit by the central canal aerial sounds, from a limited spot: it is thus of great use in distinguishing pectoriloquy from diffused bronchophony. I find that the same object can be pretty well attained by reversing the new stethoscope, applying the ear end (u) to the chest, and the hollow end (A) to the ear: this end having some extent of flat surface, fits the ear very well, and is not hollow enough to produce much conchal sound.

An inconvenience at first experienced with this instrument was its fragility, being easily cracked or crushed in the pocket. This evil is readily obviated by making the ear end (u, as seen in fig. 2) to take off and to fit into the hollow end (A); which thus not only strengthens the thin part, but also renders the instrument more portable. For this purpose, and for that of shutting out diffused sounds, the ear end should be made stout, and of a tough material, as box or yew wood.

The stethoscope in its packed or portable state (fig. 2) is well adapted to render visible the extent and direction of the pulsations of the heart or arteries, and of the motions of respiration. Held by its broad end as a base firmly applied to the chest, its small end exhibits, in an exaggerated degree, the movements of its base. Laennec used to exhibit the impulse of the heart by the lifting of his stethoscope; but this instrument does this much more exactly, and likewise shews the direction of the impulse.

As the flexible stethoscope has been recommended by some respectable authorities, (although I believe that it is very little used,) I take this opportunity to state my objections to it, which are founded on considerable experience in its use; for since Dr. Stroud, who first employed it, recommended it to me seven or eight years ago, I have given it repeated and varied trials. When tried by a test sound, I have found it much inferior in conducting power, for all the more delicate sounds of the breath and heart. Louder sounds, such as those of bronchial or cavernous breath and voice sounds, it exaggerates by the addition of a conchal echo, which renders it very difficult to distinguish them from each

other. It is much better adapted for the heart sounds, and is certainly the best instrument for exploring venous and arterial murmurs, because it may be applied with a less degree of pressure than the common stethoscope. The chief advantage, however, is in its flexibility, which permits it to be applied to the patient in postures in which the straight stethoscope can scarcely be used. On the other hand, it has the inconvenience of requiring the use of both hands to keep it applied; so that the auscultator has no hand free to prevent the friction and contact of the clothes, &c., or to steady himself whilst he leans over the patient. On the whole, although I often employ the flexible instrument for particular purposes, I am of opinion that no one who uses it only can be an accurate auscultator.

Percussion.

Since I explained the principle of percussion in 1835, I have had almost daily opportunities of proving the accuracy of that explanation, and of deriving advantage from the varied modes of percussion which the clear understanding of the principle suggested. So delicate do I now find this test, that in many instances it discovers disease when other physical signs are negative.

The principle is briefly this: sound on percussion is derived from the elastic tension of the bodies which the stroke reaches, and depends on the conjoint vibration of these. Thus gentle percussion, and flat percussion, reaches the superficial parts only, and is toned by them: forcible percussion derives its sound from deep-seated parts also.

The character of the stroke-sound varies not only in loudness and clearness, but also, and most constantly, in *pitch*; the *deepest tones* being the healthiest in all cases, except a few of flaccid emphysema and pneumo-thorax. In some cases of pneumonia, pleurisy, and even tubercle, the stroke sound is much louder on the diseased than on the healthy side; this is where the clearness proceeds from the resonance of the subjacent tubes, which the condensation of the tissue of the lung enables the stroke to reach. But in all these cases the morbid character of the sound is proved by its note being higher than on the healthy side.

In cases of early phthisis, in which the auscultator may be doubtful as to the comparison of stroke-sounds of corresponding points on both sides, he may sometimes be assisted by applying his ear to the chest at the same time that he strikes. Thus, in exploring below the clavicles, he may use gentle immediate percussion there with the fingers, whilst he applies his ear in the scapular region; but on comparing the sound with that of the opposite side, he must be careful to listen, as well as to strike, on corresponding points. Explored in this way, the clearness or loudness of the stroke is less easily distinguished than the note or pitch, the difference of which is sometimes manifest when it is not so in the usual mode of examination.

In percussion of the abdomen, it is useful to employ different degrees of pressure with the pleximeter or the hand struck. Strong pressure with forcible percussion, displaces the superficial contents (gas and liquid), and elicits the sound of deep-seated parts. On the other hand, the gentlest percussion, without pressure, will detect the superficial dulness of a layer of serum too thin to be palpable by fluctuation.

For general purposes, I consider the fingers to be the best instruments for percussion; and the various ways in which they may be used constitute one of their best recommendations. There are, however, a few cases in which an instrument for percussion will give more accurate indications; and I will describe one which is very efficient as well as very simple.

Perussion-plates, generally, are too large to be applied closely between the ribs; and when made of hard materials they cause a clacking noise by the stroke on their surface. The hammers of Drs. Burne and Winterich are not only formidable in their appearance (that of Dr. Burne is really frightful), but their strokes may vary in force, and their sounds in character, according to the direction in which the hammer falls, whether quite perpendicularly or not.

To avoid these objections, I have for a pleximeter a stout narrow piece of whalebone (about four inches long, Fig. 3), slightly bent by heat, so that one end forms a handle, whilst the other is applied to the chest;

the latter part may be covered with buff leather and velvet, to deaden the clack of the surface. The hammer (Fig. 4) is made of an oblate spheroid of lead (three quarters of an inch in long diameter) also covered with leather and velvet, with a small rod of whalebone (four or five inches long) for its handle. The pleximeter fits like a finger on or between the ribs, and is firmly and conveniently applied to any part. The hammer head being circular, like that used by geologists, can scarcely vary in the direction of its stroke, and has weight enough to elicit deep-seated as well as superficial sounds with very little force of stroke. The elasticity of the handles of both greatly facilitates their operation.*

Dec. 1842.

DROPSY IN EARLY LIFE.

To the Editor of the Medical Gazette.

SIR,

THE following case of dropsy occurring in early life, with its dissection, appears to possess some points of interest, and I should feel obliged by its insertion in your journal.—I remain, sir,

Your obedient servant,

COTTON BELCOMBE.

Minster Yard, York, Nov. 8, 1842.

Rebecca Berry, ætat. 13, from the Grey Coat School, admitted in the York County Hospital under the care of Dr. Belcombe. The girl had no complaint of illness up to the period of her admission. Had taken her meals, and done her tasks as usual; but her body being accidentally discovered to be enlarged, my father, as physician to that institution, was requested to see her by the surgeon, Mr. Short, and perceiving a distinct fluctuation, he recommended her removal to the hospital. She was placed upon a course of mercurials and diuretics, without the slightest effect; and the abdomen increasing so rapidly as to cause much distress, it was determined on consultation to have recourse to paracentesis, which was accordingly performed, and seven quarts of a pale, yellow, clear, serous fluid withdrawn. On examination, after the operation,

* These instruments may be obtained from Coxeter, near University College, and from Grumbridge, 42, Poland Street.

the liver was found considerably enlarged, projecting for some distance below the ribs, and crossing over into the left hypochondrium. The plan adopted for reducing this viscus, though steadily persevered in, had no effect; and on the 12th of August, the necessity of paracentesis being sensibly developed, it was again performed, and eight quarts of a similar fluid withdrawn.

On Sept. the 5th, ten quarts were removed. Symptoms of general distress of the system now unfolded themselves; but, in spite of all attempted measures of relief, it was deemed absolutely necessary on the 22d again to have her tapped, when eleven quarts of a fluid, redder at first than the preceding, afterwards of the same character, came away. For the first time she bore the operation badly: fainted twice, had a shivering fit upon being removed to bed, and appeared much exhausted. She died the next day at 10 A.M. The inspection was made twenty-four hours after death by Mr. Procter, the house-surgeon, who has kindly furnished me with the details.

Autopsy.—On opening the body a considerable quantity of bloody serous fluid escaped. Peritoneum thickened, of the dull pinkish-red colour of strumous inflammation, granular and roughened to the feel, covered with white specks (apparently of deposited lymph) about the size of a split pea; the mesentery and transverse arch of the colon were firmly adherent to the abdominal parietes: the intestines were of the same colour, but only adherent in some places. *Kidneys:* these were rather congested, but perfectly healthy in structure, though rather smaller than is usually the case. *Liver:* this viscus extended laterally across the epigastric to the left hypochondriac region, and into the right hypogastric and umbilical regions. Right lobe was chiefly enlarged; its anterior surface was hard and tuberculated; its colour externally reddish pink, with the peritoneal covering much thickened. Inferior surface was occupied by a large cyst about the size of a foetal head, arising apparently from the lobulus Spigelii. Fluctuation was quite distinct. Projecting from the right edge, but placed rather inferiorly, was another cyst somewhat less in size. On opening the larger cyst, it was found filled with a yellow viscid fluid,

in which floated numerous small hydatids (the hydatid acephalocystis) of a round form, and varying from the size of an ordinary shot to that of a pea, translucent, and containing a clear fluid, like water: they were all perfectly distinct. The parietes of the cyst were firm; the external coat being dense and fibrous, the internal soft and pulpy. On cutting into it, the contents quickly exuded, as if the cyst was in some measure contractile: within this cyst was a smaller one, quite unattached, and readily torn: it had a white but soft external coat, and an internal, rough and spongy: it contained a yellowish watery fluid, in which small portions of lymph floated. The lungs and heart were perfectly healthy, and of the usual size.

One point observable in the case appears to be, such a remarkable growth of disease taking place with so little sensible effects upon the general economy. The most minute inquiry has failed to obtain any supposition that the girl was ill up to the time when the increase of size in the abdomen was accidentally noticed. Hydatids have been often described as connected with disease of the liver; but I am not aware of their having been detected in a child so young; and I have looked over several pathological writers in vain for any account of an ascites requiring the operation of paracentesis at such an early age.

MERCURY IN ILIUS.

To the Editor of the Medical Gazette.

SIR,

If you should deem the accompanying case, evincing the value of crude mercury in "Ilius," of sufficient importance for your pages, it will oblige, sir,

Your obedient servant,

T. G. ATKINSON.

Wakefield, Nov. 10, 1842.

Samuel Pass, æt. 8½, the subject of this note, was first visited by Messrs. W. and S. Holdsworth, surgeons of this town, on Tuesday, the 13th of September. The following symptoms presented themselves to their notice.

Incessant vomiting, nothing remaining on the stomach; abdomen much distended; violent pain round the um-

bilious; constipation for three days previous to this date; no increase of pain by pressure; and, by further enquiry of his mother, she alleged the fact of his being in the habit, (for amusement sake) of standing on his head occasionally during the last few weeks; leading to the conclusion that the case was one of obstruction of the bowels.

The treatment consisted in the administration of croton oil, and other drastic cathartics, with various "enemas," and the patient continued in this state, with the exception of the first enema bringing away a quantity of scybala, until,

16th, Friday; when all the symptoms were augmented, with the addition of his now vomiting feculent matter. Tobacco infusion of double the usual strength was given by enemas, but came away unmixed with faeces, soon after having been injected.

17th, Saturday.—Was bled this morning, in order to relax the parts if possible. Complete syncope did not succeed the venesection; blood did not evince inflammatory indications.

When I first saw him on this day, his pulse was quick and feeble; strength greatly prostrated; countenance anxious. His case appeared hopeless.

We ordered him brandy, and other stimulants, and four ounces of quicksilver, which dose was repeated during the evening, four hours after the first. The mercury was rejected from the œsophagus once or twice before it would reach the stomach. He never vomited after this day; except some milk, which he was improperly allowed to take in too large a quantity; but the other symptoms were not much alleviated.

19th, Monday.—On this day eight ounces more of quicksilver were given with henbane, to alleviate the spasm. The mercury at first caused an increase of pain, but in the course of three hours all his symptoms were at once relieved, although the bowels were not evacuated until the

22nd, Thursday; when a copious stool was passed; since which time he has gradually recovered, without any drawback. Thirteen ounces of the quicksilver have passed at intervals during the succeeding fortnight.

The peculiarities of this case seem to be—1st, the origin of the disease;

2d, the fact of the relief of the symptoms as soon as the mercury appeared to reach the obstructed part, although no stools passed per anum for three days after this period.

EFFECT OF MENTAL IMPRESSIONS ON DISEASE.

To the Editor of the Medical Gazette.

SIR,

IF you deem the following cases and remarks, illustrative of the effect of mental impressions on bodily disease, worthy of a place in your valuable journal, they are at your service, and

I am, sir,

Your obedient servant,

JOHN HITCHMAN.

Dec. 9, 1842.

R. T., an active man, single, æt. 21, had been suffering two days and a night from pain in his bowels, accompanied by vomiting. Calomel and opium had been given, and hot fomentations used without success. The pain and sickness continued. When I saw him he was resting on his back with his knees drawn upwards. His countenance indicated pain. He complained of being exceedingly weak, and of pain in his bowels. The skin was hot and rather dry; the pulse small, contracted, and quick,—120 in the minute; respiration difficult and frequent; the tongue rather dry and white; sickness after taking any thing; bowels costive; urine scanty; had been wayward during the night, and complained of headache at the time of my visit; no derangement of the pupil; no intolerance of light, no tinnitus aurium. The stethoscope revealed no pulmonary disease. On placing my hand upon the seat of pain, the umbilical region, I found the integument very hot, and the pain much increased by pressure. I viewed this as a case of peritonitis, and proposed an immediate loss of blood by venesection. To this the patient strongly objected. Leeches were then recommended, but of these he was equally afraid. On strongly urging, and insisting on these, the patient became much frightened, and partial faintness followed. The pulse permanently fell, and from that moment the pain and sickness disappeared; the bowels were acted on, and

in a few days the patient was quite well, without the loss of a single drop of blood. No calomel had been taken for thirty-four hours prior to this, so that the result may be fairly ascribed to the mental influence.

The next case is of a different character, and came under my notice on Nov. 21, 1841.

J. T., æt. 47, married, had been ill for six months. He now laboured under the impression that he had syphilitic disease accompanied with a discharge from his urethra. After gaining his confidence, I found that he had been professedly a religious character, but that in a frail moment he had yielded to the charms of a prostitute, and violated his marriage vow. Remorse followed; he could not sleep; walked about the room at night; neglected his business, and from a cheerful, became a gloomy man. As he concealed the cause, his altered conduct was attributed to mental derangement. After a time dyspeptic symptoms set in, and these, under the influence of an upbraiding conscience, he metamorphosed into, or rather imagined to be, "the foul disease." This increased his mental distress, and his conduct became so strange, that medical advice was called for. As the patient did not reveal the cause, his conduct, and the representations of his family, deceived the medical attendant, and he regarded it as a case of mental derangement. Bleeding to a great extent was resorted to, in opposition to the patient's will. His remonstrances, and his passionate resistance to being bled, were so many additional proofs of his insanity. He was in the constant habit of pressing his urethra to detect a discharge, and as he occasionally found a very slight moisture, the result of his own irritation, he was confirmed in his erroneous impressions; and when after weeks had elapsed he expressed his fears as to the real nature of his malady, (without admitting his by-gone guilt), and the parts were found quite healthy. This was deemed another delusion, (as it most certainly was) and monomania. It was an erroneous impression on the part of the patient, but the misery occasioned by it, and the treatment to which he had been subjected, had so undermined his health, that when I saw him his mind was despon-

dent; his countenance was pallid; his muscles weak and flabby; his tongue furred; his breath offensive; his respiration easily accelerated; his pulse languid, and occasionally intermittent; and his feet were swollen. His bowels were acted on daily, but there was tenderness over the right hypochondrium, and the urine deposited a pinkish sediment (parpurate of ammonia?) on the vessel which contained it. He had been salivated six weeks before. I examined the organs of generation, and found no trace of syphilis, or the presence of gonorrhœa; but knowing that it was impossible to convince him, other than that his symptoms were "the foul disease in his blood," I assured him it would be removed by injecting a fluid into his urethra. This pleased him much. A syringe was provided, and an injection, consisting of a pint of water, and five drops of *sp. lavand. comp.* Of this he used a syringeful three times a day. The history of the case suggested the treatment. The dyspepsia following, not preceding the remorse, his erroneous impression arising out of the bodily ailment, being confirmed by it subsequently (aided by a clear knowledge of having run the risk of contagion), his unwillingness to confess the primary cause of his distress to his family medical attendant, while he readily did this to a stranger, induced me to try to soothe the mind by attending to his ideas, though erroneous, rather than attend exclusively to the corporeal feelings, however real and evident. In the meantime he took grain doses of blue pill, with a grain of ipecacuanha and three of rhubarb at night, and the following mixture in the day.

℞. Decoct. Aloes Comp. ʒij. ; Spt. Ammon. Aromat. ʒiiss. ; Mist. Camphor. ʒv. ʒvjss. M. Cap. 6tas partes bis in die.

Under its use, with a moderately nutritious diet, his mind, from being restless, desponding, and suicidal, became tranquil and cheerful, his bodily health returned, and in a few weeks he was fit to pursue his ordinary duties as a shoemaker. The pills were continued a week and the mixture a fortnight, but to the injection he ascribed all his benefits; and the probabilities are, that without it, something appearing directly to combat the imaginary

disease, no good would have been effected by medicine, however appropriate to the disordered state of the chylopoietic viscera.

FATAL DISEASE INDUCED BY HYDROPATHIC TREATMENT.

To the Editor of the Medical Gazette.

SIR,

IF the enclosed case, with the remarks, be considered worthy of insertion in your periodical, it is quite at your service.—I am, sir,

Your obedient servant,

THOMAS H. SILVESTER, M.D.

29, Sackville Street, Dec. 12, 1842.

The science of medicine is so extensive, and the facts on which it is founded are so numerous, that it would appear to surpass the powers of the human mind to master, and to entirely comprehend, the whole subject; and yet a German peasant, buried in the obscurity of the mountains of Silesia, pretends to have discovered not only the spring of every morbid action in the human frame, but a sure and certain cure likewise for all the diseases which human flesh is heir to.

The following case will be sufficient, I think, to convince any reasonable person that the hydropathic system of treatment is not always unattended with danger: one may even go further, and declare, that in the present instance a disease of an acute and mortal character was engrafted on that for which the water had been prescribed.

A gentleman who had been residing at a hydropathic establishment on the Rhine, and had gone through the whole process of "the cure," as it is called, returned to this country still suffering from the peculiar eruption or crisis. He said, that nothing could be more pleasurable and exhilarating than the various kinds of baths employed, and that he seemed to derive much advantage from their use. The internal administration commenced by the patient taking two tumblers of water during the day; the dose was gradually increased until it amounted to twenty-five tumblers in the same period. Abscesses began at the end of a month to make their appearance on several parts of the body; these were exceedingly painful, so much so as to

render his days wearisome and his nights sleepless: he was told, in answer to the complaints which he made on this head, that the eruption constituted the crisis, and that the morbid elements having undergone the necessary coction, were about to be eliminated, and cast out of the system through these artificial channels, and that, instead of sympathy, he deserved the congratulations of his friends at the fortunate termination of his disease, and consequent restoration to perfect health. He determined, however, after having suffered great pain, with feverishness and exhaustion, for nearly a fortnight, to return home. This he accomplished with some difficulty. I visited him immediately on his arrival. He first drew my attention to an abscess on the wrist; it was of a livid hue, about as large as a walnut, exquisitely tender to the touch, and a bloody sanies streamed from several distinct apertures on its surface.

Another, of a similar character, but as large as a hen's egg, was situated in the perinaeum; a third, of almost equal size, occupied the pubic region: many others were to be seen on the body and extremities. They did not, in their mode of distribution, appear to submit to the law of symmetrical arrangement: not one was to be found on the left half of the body. Interposed between the larger specimens were many of smaller size, and some so diminutive as scarcely to deserve the name even of abscesses, being merely deposits of pus under the cuticle. Every effort was made to restore the debilitated constitution of the patient; but in vain. Abscesses continued to break out anew, about the hand and wrist; the absorbents became inflamed, along the internal face of the arm, as far as the axilla, and the patient, at length worn out with intense suffering, sank—a victim, shall I say, to the water cure?

Medicine is a science founded entirely on experience and observation; by the aid of these tests we shall soon be able to ascertain the precise value of hydropathy. One thing is very certain, that it will have to recede from its present high pretensions, and to undergo great modification, before it can be regarded as a valuable addition to our rather heterogeneous stock of remedies.

HERNIA AT THE OBTURATOR FORAMEN.

To the Editor of the Medical Gazette.

SIR,

I beg leave, with your permission, to put upon record in your journal the following rare case, which lately fell under the notice of myself, Dr. Allen, and John Lawrence, Jun. Esq. surgeon, of this town.—I am, sir,

Your obedient servant,
W. KING, M.D.

Brighton, 10th December, 1842.

Mrs. W., æt. 76, the mother of several children, had complained for about a year of pain in the left groin, in the course of the obturator nerve, and of cramp in the left thigh and leg. About a fortnight before her death, she was seized with pain in the lower part of the abdomen, vomitings, not stercoraceous, and total stoppage in the passage of the bowels. On examination after death the following facts appeared. Adhesion of the lower edges of the omentum to the edges of the bladder and left rim of the pelvis; hernia of the small intestine at the obturator foramen, strangulated between the bone and the obturator externus muscle, and beginning to slough; the nerve and artery lay behind; acute peritoneal inflammation of the small intestines, but no lymph or effusion.

The preparation is deposited in the Museum of the Brighton Hospital.

A concise account of the few cases on record may be seen in Mr. Lawrence's book on Ruptures, chap. 23, 2d edition, 1810.

CASE OF

DISLOCATION AT THE KNEE-JOINT.

By FRANCIS ADAMS, Esq. Surgeon.

(For the Medical Gazette)

SEPT. 10th, 1842.—Alexander Robie, æt. 55, while in the act of carrying provender between two large bullocks in their stall, was knocked down by a stroke of one of their hind legs on the right knee, and while lying on the ground was severely injured by being trod upon in several parts of the body, especially near the middle of the right leg. I saw him about two hours after the accident, and found the bones of

the leg lying on the fore part of the femur, so that the cuticular cavities could be distinctly felt, while below the contour of the condyles could be evidently traced: in short, I never saw a case of dislocation in which the symptoms were so strongly marked. The patella was pulled considerably up the thigh, but it appeared pretty obvious that neither the *ligamentum patellæ*, nor the tendon of the quadriceps, was torn. The limb was extended. From the mobility of the parts, and the great separation between the ends of the tibia and femur, I was impressed with the conviction that the lateral and other principal ligaments of the joint must be torn. By making extension and counter extension, the reduction was effected with little difficulty. The limb was then bandaged loosely from the toes to near the middle of the thigh, and laid half bent on a thick pillow, and evaporating lotions directed to be applied occasionally. For some days, no severe symptoms occurred in the joint; but swelling and suppuration having taken place in the leg, especially about its calf, the bandages had to be removed, and poultices applied. The limb continued very much swollen, with fetid discharges; and owing, perhaps, to its weight, the bones of the leg, about the twelfth day, were dragged downwards, so as then to give the knee-joint the appearance of a semi-luxation backwards. The limb was secured in the best manner that could be done in its tender state, and the bones retained in position by means of a jointed splint applied below the thigh and leg.

30th.—The limb has gone on daily getting into a worse state; the foot has lost its heat and sensibility, and the whole leg behind up to the knee is of a darkish-green colour. About the calf of the leg it is greatly swollen, and the discharge from it very copious. The joint is so loose that the bones can with difficulty be kept in position; the pulse about 115. He has agreed to have his limb removed next day if no improvement takes place in the interval.

Oct. 1st.—I amputated the limb to-day about the middle of the thigh, with the assistance of my professional neighbour, Mr. Walker. The patient bore the operation with great fortitude, and appeared, soon afterwards, much relieved from his sufferings. The mus-

cles felt so soft and flabby as to excite apprehensions, in my mind, that the vessels might not bear the ligatures well: no unpleasant symptoms, however, occurred, and the stump was completely healed in the course of three weeks.

We examined the parts about the knee-joint immediately after the operation. As I had formerly supposed, the tendon of the *quadriceps* and *ligamentum patellæ* were entire; the latter, however, much stretched and slackened; and, contrary to my expectations, I also found the lateral ligaments much torn. Upon cutting into the joint, the crucial ligaments were found to be torn in pieces, but all the other parts were uninjured; the posterior ligament, the heads of the gastrocnemius, and the popliteal vessels, being soft. The limb below being a general mass of suppuration and putridity, was but cursorily examined: it appeared certain, however, that the back part of the leg had been bruised to the state of a pulp: the condyles were somewhat smaller than natural, and were so rounded as to shew an unusual aptitude to slip out of the articular cavities; and to this construction of the solid parts, joined, perhaps, to some preternatural laxity of the ligaments, the accident may, no doubt, be ascribed.

This would appear to be one of the rarest dislocations to which the joints of the human body are subject. The only unequivocal case, which I know of as having been reported in this country, is the one related by Mr. Jonathan Toogood, in the *Provincial Medical Journal*, June 1842. Another, supposed of a similar nature, reported by Mr. Coote, he regards as probably incomplete. In these two cases recovery took place without any untoward symptom; as I have no doubt would have happened to my patient, had the injury been confined to the knee-joint. Mr. Toogood mentions, that neither Sir Astley Cooper, Dupuytren, nor Roux, had ever met with such a case, nor, as far as I can discover, do any of our latest writers on surgery mention having ever had occasion to treat this accident. Cheselden, although correct in stating that "the knee cannot be completely dislocated without breaking the *cross ligaments*" (Annot. p. 45) may be supposed, from the problematical way in which he expresses himself, to have

had no experience of such a case. Boyer also writes of the accident in equivocal terms, and is wrong in stating, that the heads of the gastrocnemius, and other soft parts, must necessarily be torn. Of the ancient authorities in surgery, Celsus alone makes mention of dislocation forwards: he says, "in priorem non prolabi plerique scripserunt: potesque id vero proximum esse: cum inde opposita patella ipsa quoque caput tibiæ continent. Meges tamen cum cui in precorem partem excidisset, a se curatum esse memorie prodidit." *Med. viii.*, 21. Hippocrates, the great ancient authority on fractures and dislocations, describes dislocations of the knee outwards, inwards, and backwards, but says nothing of dislocation forwards: and all the other ancient writers on medicine, both Greek and Arabian, report the same statement. In like manner, the earlier surgical authors in modern times, being all servile copyists of the Arabians, give the same account of dislocations at the knee—see Theodoricus, lib. ii., c. 52. As far as I can learn, the case which I have now related is the only one on record in which the state of the parts was ascertained by dissection.

Banchory, near Aberdeen,
Dec. 8, 1842.

ON THE
VALUE OF THE CORPUS LUTEUM
AND DECIDUOUS MEMBRANE
AS TESTS OF EARLY
PREGNANCY.

To the Editor of the Medical Gazette.

SIR,

IF from conviction I could alter my opinion on Dr. Paterson's corpora lutea, it would afford me the greatest satisfaction to do so: for I know from experience, that the pleasure of renouncing an error is only equalled by the delight felt on discovering a new truth. "A lamp-lighter," says Dr. P. "residing in the Cannongate, was indicted for the murder of his wife. It appeared that the parties had been married eight years, and had had no family. The man was a sober and decent person, while the woman was addicted to the use of spirits. Latterly she had become acquainted with a young man, whose frequent visits to her, in the ab-

sence of her husband, excited suspicions against them. This man (husband ?) in a fit of passion and jealousy, inflicted on her wounds which proved fatal. The uterine organs were removed at the inspection, and examined afterwards. The right ovary presented externally an enlargement of the size of an ordinary marble, of a dark purple colour, having several minute vessels ramifying on its surface, a distinct depression in its centre, and the appearance of a minute cicatrix. On cutting into it, the structure and appearance of a very early corpus luteum was observed, which was formerly described. The uterus contained an extremely soft decidual membrane, *but no ovum could be detected*, although minutely and carefully examined. Indeed, although this person had conceived, there can be little doubt, from the puckered and contracted appearance of the fimbriated extremities of the fallopian tube, which would hardly admit of a small probe to enter, that no ovum could have passed into them. In this case it is possible that the woman had conceived by her husband ; but it is more probable *that she had not*, and that the husband had great cause of provocation." "But let us suppose," adds Dr. P. "that the husband had been absent for a month or so, and had inflicted similar blows on his return, it would have become a question of the greatest importance to have determined not only if that was a true corpus luteum, but whether or not it was possible to have been produced—the result of a conception before his departure. Although this case is in so far imaginary, yet the circumstances supposed are very likely to have happened, and the appearances observed in the ovary, if carelessly examined, would either have been set down on the one hand as a clot of blood, or as bearing at least none of the marks of the corpus luteum as described by authors."

It is inferred from this singular history, although no ovum, nor any vestige of an ovum, could be detected on the most minute and careful examination, neither embryo, vesicula umbilicalis, amnion, nor chorion, that this murdered woman was pregnant, and that she was an adulteress. Not only is the pregnancy considered a fact of absolute certainty, but the red clot of blood in the ovarium, which does not present one

of the characters of a true corpus luteum, into the composition of which there does not enter a particle of yellow matter, is described as a corpus luteum "a very short time after the rupture of the Graafian vesicle and escape of the ovule." An ovule, which was never seen, is presumed to have escaped from this ovary, but, on dissection, though hunted out with the greatest care, it was no where to be found. My conscientious belief is, that a fecundated ovum never existed here at all, and that this woman, who had lived eight years with her husband and was barren, and whose internal uterine appendages were in a state which rendered pregnancy impossible, or at least highly improbable, died during menstruation. I have so often seen all the appearances here described in the ovaria and uterus of women who have never been pregnant, that I have no doubt of the fact. If I were summoned into a court of justice, I would have no hesitation in declaring upon oath, from the evidence furnished, that the proofs of pregnancy were wholly wanting. With this deep conviction upon my mind, I could not avoid drawing the attention of my class to this case, and imploring them to be cautious how they gave evidence in courts of law to criminate unmarried women who have committed suicide, or died suddenly from any cause. Upon no other ground would I have considered this case deserving of notice or criticism, for, as far as the structure of the corpus luteum is concerned, it proves nothing. Nobody has come forward with a testimonial in behalf of this corpus luteum, or asserted, that he saw two membranes around the coagulum of blood, and a layer of coagulable lymph in the centre, filled with a reddish grey-coloured fibrinous matter. The character of this corpus luteum is, in truth, gone for ever—far more completely blasted than the reputation of the poor lamp-lighter's murdered wife.

"The third figure," I observed, "represents the appearances presented by an ovarium removed from the body of a woman who died of chronic disease of the brain. Here also no ovum could be detected by Dr. P. in the uterus, upon minute microscopic examination to determine that pregnancy had actually taken place, although he infers that "impregnation had occurred

from a fortnight to three weeks before death. If you examine this figure you will see that there is no capsule interposed between the yellow matter and stroma of the ovary: and the same is the case with the fourth figure, [exhibiting it] which represents a *true corpus luteum* in the second month of pregnancy. Dr. Allan Thomson says, in his description of the corpus luteum, that a cavity existed in the interior of this corpus luteum similar to what is seen in all true corpora lutea: but Dr. Paterson says this statement "is erroneous, as its centre was filled up with a reddish grey-coloured fibrinous mass. In figure 5 the Graafian vesicle is seen distinctly within the yellow matter, and this, you see, is in immediate contact with the stroma of the ovary, although Dr. Paterson says, in his description of it, that external to the yellow body was also a firm membrane."

Dr. Reid, of St. Andrew's, vouches for the authenticity of these three last corpora lutea, though no ovum was found in the uterus connected with the first; but he prudently abstains from committing himself with the others. Dr. Reid affirms that Dr. A. Thomson was perfectly correct in stating that there was a central cavity in the fourth corpus luteum, "though," he adds, "there can be no doubt, as any one may readily satisfy himself by looking at the preparation in my possession, that there could be none;" and that Dr. Thomson meant only to say "that the true texture of the corpus luteum occupied the surface of the body only, and did not extend through the centre."

But Dr. P. says, "the uterus of this case (woman?) was a little enlarged, and contained an extremely thin and soft decidual membrane." The utter worthlessness of the decidua, as a test of pregnancy, found "in the uterus of this case," (!) will easily be estimated from the following quotation from Dr. Blundell's Lectures, and also the real value of the microscopical researches determined, which have led to the revival of an antiquated and exploded error, viz., that the decidua is nothing but the altered mucous membrane of the uterus." The decidua is sometimes produced in cases of difficult menstruation; and it is important to remember that it may be mistaken for abortion. It resembles it in the pains, discharge of blood, &c. *But the*

one presents an embryo at various stages of increase, while in the other that is altogether wanting. It seems now agreed, that the discharge of this membrane (recognised by Dr. Baillie to be similar in structure to the decidua) occurs frequently in unmarried females. It would appear to be generated spontaneously by the inner membrane lining the uterus." I could quote twenty other authors of reputation to the same effect, if I had time, or considered it worth the trouble.

I am, sir,
Your obedient servant,
ROBERT LEE.

14, Golden Square, Dec. 12, 1842.

ON MYOPIA.

By W. CLAY WALLACE, M.D.

New York.

(For the London Medical Gazette.)

THE average point of distinct vision is from fifteen to twenty inches from the eye. When an individual cannot see distinctly at this distance, but requires to hold the object nearer, he is said to be short-sighted; or if he must remove the object to a greater distance, he is said to be far-sighted.

Causes of myopia.—The causes of this defect have been usually ascribed to—1. too great convexity of the cornea; 2. too great thickness of the cornea; 3. too large a size of the anterior chamber; 4. unusual convexity of the crystalline lens; preternatural density of any, or of all the transparent media; 5. preternatural elongation of the eyeball; 7. a dilated state of the pupil; and 8. alteration of the position of the crystalline lens.

1. Too great convexity of the cornea may, and often does, produce near-sightedness; but "it is also certain," observes Dr. Mackenzie, "that this conformation is by no means a *common*, nor even a *frequent*, attendant on the disease."

2. It is not probable that unusual thickness of the cornea is ever of itself the cause of the complaint.

3. Too large a size of the anterior chamber would, if that were all, remove the crystalline farther from the cornea, and thus produce far-sightedness.

4. Percy and Reveillé Parise exa-

mined the eyes of subjects who had been short-sighted when alive, without being able to observe unusual convexity of the crystalline: besides, myopia and presbyopia are sometimes suddenly produced, and sometimes suddenly removed—effects which could not possibly take place if the complaints arose from altered configuration of the refractive media.

5. Though the eyes of myopes are firmer than usual, it would be difficult to shew that the media are so increased in density as to produce the complaint.

6. No case of myopia arising from preternatural elongation of the eyeball, unaccompanied by conical cornea, or partial staphyloma, has been shewn to exist.

7. We often observe the pupil to be preternaturally dilated, without near-sightedness; besides, if the aperture be expanded by stramonium or belladonna, an opposite effect, or far-sightedness, is produced.

8. From what follows it will be seen that malposition of the crystalline is the most frequent cause of the complaint.

For a clear understanding of the causes of myopia and presbyopia, it is proper to inquire into the method by which the eye is accommodated to different distances, as the necessity for some means of adjustment is proved by the analogy of the organ to other optical instruments, and by a number of experiments.

Adjustment has been referred—1. by some to alteration of the diameter of the pupil; 2. by a few to muscularity of the crystalline lens; 3. by a greater number to pressure of the external muscles changing the convexity of the cornea; and 4. to alteration of the position of the crystalline lens.

1. Since the days of Baptista Porta it has not been denied that the eye is constructed on the same principle as the camera obscura: consequently, alteration of the diameter of the pupil can have no more effect in adjusting the eye, than alteration of the diameter of the aperture of a camera obscura in producing a distinct image, which is solely effected by sliding the lens backward or forward till it is brought to a focus. When a person endowed with the usual powers of vision looks at a near object, the pupil is observed

to contract; whereas, in a myope, it is often preternaturally expanded.

2. The fibres of the crystalline lens are totally different from muscular structure; and if they really did possess contractility, there is no point of attachment from which they could act. In a certain species of hawk, the crystalline is a plano-convex, and it is in all animals so exquisitely cut, if I may use the expression, that the irregular action of muscles would produce irregular refraction. In aquatic animals, where the crystalline is dense, the fibres are separated from each other with so much difficulty, that it is not probable they could slide over each other in such a manner as to produce the effect. Moreover, Sir D. Brewster has ascertained that in these animals the fibres of the crystalline are locked or dove-tailed into each other by a species of teeth, which would prevent any change in the configuration of this refracting medium.

3. The external muscles of the eye are adapted solely to move the organ in different directions. If adjustment depended on them, the focus would be disturbed with every motion; whereas we can look steadily at an object, and even roll the orbit round the eye, without changing the image on the retina. After the operation for strabismus, the eye can be adjusted as well as before it, even when one of the obliqui has been divided, and after the operation for cataract, though the muscles and the cornea are as perfect as ever, the power of adjustment is lost; glasses of different powers being necessary to view near or distant objects.

It is admitted that the eyes of all animals are constructed in adaptation to the known laws of the refraction of light; that rays will deviate from straight lines, and be collected in a focus, only when they pass to a denser medium. Now, granting that pressure of the external muscles produced increased convexity of the cornea, rays of light proceeding from an object under water to the eye of an animal inhabiting the same fluid would not by that means pass to a medium materially denser, and would not be sufficiently refracted to make any change of adjustment. The very dense and convex crystalline of an animal which inhabits the water is the only medium

by which the rays can be collected in a focus on its retina. Increased convexity of the cornea could not be produced in the eyes of some animals, for the sclerotica is occasionally so firm, that no pressure of the external muscles could alter the form of the cornea. In the sturgeon the sclerotica is cartilaginous, and in thickness about one-fourth of the diameter of the eyeball; while firmness is given to the sclerotica of the sword-fish by a covering of bone.

4. When the camera obscura is directed from a remote to a near object, it is customary to adjust the instrument by drawing forward the lens rather than by altering the position of the ground or screen. The opinion that adjustment is effected in the eye by the same means, was advanced by Kepler, and supported by Porterfield, and afterwards by Knox, though neither of them has satisfactorily explained how the change could be effected.

It will now be shown that the crystalline is made to approach nearer the cornea when viewing near objects, and to recede from it when viewing distant objects; and consequently, that myopia and presbyopia frequently arise from malposition of the same refracting medium; or, in other words, that the crystalline is placed too far forward in the former, and too far backward in the latter complaint.

The form of the crystalline in animated beings is either a double convex, a plano-convex, an oblate spheroid, a sphere, or a prolate spheroid. When the crystalline is a perfect sphere, there is no aqueous humour, there is no canal of Petit, there are no ciliary processes, nor ciliary muscles. The sphere is suspended by a filament, and kept in position by the membranes of the vitreous humour, some of which pass through a slit at the lower portion of the retina, and are fixed to the choroid. Attached to the capsule covering the lower portion of the sphere there is a muscle which, though it varies in shape and size, is very conspicuous in the halibut, the striped bass, and the dolphin. In the halibut it is hatchet-shaped, attached to the iris, and placed diagonally across the eye; whereas in the dolphin and striped bass it is triangular, and passes through a loop at the

back of the iris, to be attached to some of the membranes of the vitreous humour. This muscle is supplied by a large branch of the 3d pair of nerves, which is said to be analogous to the 5th pair of the mammalia. When the muscle contracts, the crystalline approaches the cornea, and is adjusted to near objects, while it (the crystalline) is drawn back or adjusted to distant objects by the elasticity of the membranes of the vitreous humour, the firmest of which pass through the slit in the retina before mentioned. The slight rotatory motion produced by drawing the crystalline forward, from only one point of attachment, can have no effect in varying the image, as the diameters of a sphere are always the same.

That some have asserted there is an apparatus for adjustment in fishes is stated by Porterfield, who denies that there is any such arrangement, though he does not mention the name of the author. In my published papers I have stated, that the body attached to the crystalline had been noticed by Haller, by Cuvier, and others. I pointed out its muscular appearance, its being supplied with a distinct nerve, its attachments, and evident use. If some of my publications have been premature, I am not alone, for in the London Magazine of Natural History for 1838, there is the following statement by Professor Dahrymple, of Sydenham College:—

“Some few years ago, while examining the organ of vision in a pike (*Esox lucius*) I observed a small roundish grey-coloured body, about the size of a hemp seed, attached to the circumference of the lens; and at the same time, certainly without due consideration, I designated it a muscle, principally from the fact that I traced a nerve running from the posterior part of the eye to this peculiar body. The preparations then made I exhibited to some young American gentlemen attending the practice of the Moorfields Ophthalmic Hospital.

“That the existence of this body is unknown, in England at least, is, I think, borne out by the fact that the learned professor of comparative anatomy at King’s College, Mr. Owen, and Mr. Yarrell, so well known by his beautiful work on the ichthyology of

Great Britain, were both unacquainted with the circumstance when I mentioned it to them.

"In a number of the American Journal of Science and Arts will be found a somewhat similar account of a muscle discovered in the eye of the streaked bass, by Mr. W. Clay Wallace, Surgeon to the New York Institution for the Blind. This gentleman did me the favour to send me over, about twelve months since, his paper published in that journal. From the circumstance of my not being aware of being personally acquainted with Mr. Wallace, I cannot help suspecting that he is one of the Americans to whom the observations made by me were imparted at the Ophthalmic Hospital some years ago."

To this *suspicion* it is unnecessary to say any thing farther than that I have never seen the gentleman, nor have I ever been in London.

As the diameters of lenses of any other shape than spheres would be altered by drawing them forward from only one point of attachment, there must be some other arrangement for adjustment when the crystalline is not a perfect sphere; and that arrangement is found in the ciliary body, which does not exist in animals with spherical lenses.

When, in the customary manner, we expose the ciliary body of the ox, by removing the anterior half of the sclerotica with the cornea, we bring into view—1, the choroid, 2, the annulus albidus, and 3, the iris; but if we commence the dissection from the centre of the cornea, and make a number of radiated incisions, extending along it and the anterior half of the sclerotica, taking care not to go through the coat of Decemet, the annulus albidus, or the choroid, until about eight or ten of the incisions are completed; if we then cut completely through the cornea, and turn over the flaps, we may, with care, carry with them the annulus albidus, the portion of the choroid which covers the ciliary body, and some muscular fibres. If we now tear off the iris, the circumference of which is loosely connected by cellular membrane, we have a beautiful and instructive preparation. We observe the apices of the ciliary processes surrounding the margin of the crystalline, the attachments of the processes to the

anterior wall of Petit's canal, the grey cellular matter connecting them together, and surrounding this cellular matter two muscles resembling crescents, the horns of which meet at the equator of the eye. The muscular fibres are radiated, their colour resembles that of the legs of a frog, they are most plainly visible in the fresh eye, and in this respect they differ from the so-called muscular fibres of the iris. Each of the ciliary processes resembles a leaf, and is highly vascular. The trunks of the arteries supplying the processes pass the muscular fibres at the junction of the crescents, a spot where they cannot be affected by the contraction of the fibres; whereas the returning veins pass directly under the muscular fibres, and may be so compressed by the contraction of the latter that the processes may become erect from accumulation of blood in the vessels.

When we cut off the cornea, and that portion only of the sclerotica which covers the ciliary body, then the ciliary body and iris, and inflate the canal of Petit, we observe that the crystalline advances, and that when the inflation is discontinued, it resumes its situation. The anterior wall of Petit's canal is merely an extension of the capsule of the crystalline over the hyaloid or investing membrane of the vitreous humour, to which the circumference of the extended capsule becomes attached. The utility of the plaiting will become evident if we make two models of the eye, one with a plaited, and another with a plain anterior wall of this canal; when it will be found that the unplaited model will not work, whereas the crystalline of the other may, from the looseness of the plaits, be made to advance to a considerable extent. The use of Petit's canal appears evident; the anterior wall is permitted to pass freely forward, by there being a canal or space between it and the true hyaloid membrane, and when it advances the crystalline goes along with it.

The membranes of the vitreous humour radiate from the posterior wall of the canal of Petit, and from the posterior capsule of the crystalline, in such a way, that when the latter is drawn forward, they may, by their elasticity, draw it backward. In animals with spherical lenses, some of the

membranes of the lower portion of the vitreous humour, nearly on a line with the single adjuster, pass through a slit in the retina to be attached to the choroid. In other animals, there is no division of the retina, nor indeed any connection between it and the tunica hyaloidea, except a slight attachment at the entrance of the optic nerve.

We have thus the annulus albidus to give a firm attachment to the ciliary body, by connecting it with the sclerótica, the muscular fibres to contract the ciliary veins, the ciliary processes to become erect by the accumulation of blood, the plaited margin of the capsule forming the anterior wall of the canal of Petit to which the processes are attached, the space between this and the hyaloid membrane to allow it to be drawn forward, and the elastic membranes of the vitreous humour, to draw back the crystalline when the opposing force is removed.

The use of the ciliary body is therefore evident, from, 1. its entire absence in animals with spherical lenses where there is another instrument for drawing the crystalline nearer the cornæ; 2. the structure of its different parts; and 3. there is no arrangement by which adjustment can be explained, or by which we can account for the sudden occurrence of near and far-sightedness.

In man, though the muscular fibres are not placed in crescents round the ciliary processes, but in an entire ring, the rest of the arrangement resembles what has been described. A ciliary body always exists whenever the crystalline is not a sphere, as in quadrupeds, birds, and reptiles, where it is a double convex, or plano-convex; the shark, the porpoise, and a species of eel, where it is an oblate spheroid; and in the cuttle-fish, where it is a prolate spheroid.

Though the existence of ciliary muscles has been denied by those who have not had an opportunity of seeing them dissected, the clearness of my demonstrations has been acknowledged by some of the profession. Being concealed by the outer layer of the choroid, they escaped exposure until I discovered the above method of taking it off.

When the eye is adjusted to a remote object, and when by the external muscles we then direct it to one which is near, a confused or indistinct image

of the latter is formed on the retina; the impression is communicated to the sensorium by the optic nerves; a reflex affection of the third and fifth pairs of nerves from which the ciliary nerves proceed, causes a contraction of the muscular fibres which are arranged round the ciliary processes; the veins are compressed, and the apices of the processes which float in the aqueous humour of the posterior chamber become elongated; these, being attached to the posterior wall of the canal of Petit, will of course draw it forward; the advancement of this wall will be followed by advancement of the crystalline until a distinct image of the object is formed on the retina.

[To be continued.]

ON A
PECULIAR AND OBSTINATE FORM
OF DIARRHŒA,

APPARENTLY COMPATIBLE WITH A ROBUST
FRAME, THOUGH OF LONG DURATION.

BY D. MACLACHLAN, M.D.
Royal Hospital, Chelsea.

(For the *London Medical Gazette*)

THE form of diarrhœa to which I allude must be of frequent occurrence, though I am not aware of any monograph on the subject, and no mention is made of it by any of our systematic authors. Three cases have come under my own observation within the last three years, and I am aware of a fourth that recurred after a duration of from four to five years. It therefore merits the attention of the practical physician, and, in a pathological view, is highly interesting.

In all the cases I have met with, there has been such a striking similarity, as to leave no doubt, in my mind, that the causes of the disorder were precisely alike. On first awaking in the morning, the patient is seized with a desire to stool; he is no sooner out of bed than this becomes inevitable, and he has scarcely reached the closet ere he voids from half a pint to a pint of broken-down feces: the relief is decided, but he has not returned to his apartment before the inclination is again equally urgent: he now passes a lesser quantity, and in a more fluid state, and again he is much relieved by

the evacuation. After a number of motions, varying from two to five, the desire altogether ceases, a longer interval occurs between each, and the patient sits down, little debilitated or exhausted, to enjoy a hearty breakfast. If this is one of his "bad mornings," breakfast is hardly over when he has passed another liquid motion, and again he has a renewal of his former symptoms. Seldom, however, has he more than two, or at most three, evacuations after breakfast; and by 12 or 1 o'clock he is perfectly comfortable for the remainder of that day. His appetite is good, and he has no uneasiness in the rectum. A few articles of diet disagree with him, increasing the number of the motions, and producing occasionally flatulency. Malt liquors, beer, ale, or porter, are generally injurious, but a few glasses of wine seem to have no effect on the complaint.

The symptoms go on in this way, probably, for some years. Each morning there is a return of the diarrhœa, but, strange to say, when within bounds, when not above two or three motions are voided from the time of getting out of bed till the forenoon, the general health seems scarcely to suffer. In two of the three cases of this form of diarrhœa coming under my care, the individuals were robust and muscular. One of these had suffered for upwards of two years; he had never during that period passed a formed motion. The other patient had been affected for a much longer time, but had intervals of two or three weeks, during which, though the fæces continued liquid, they had assumed a consistency, and did not exceed one or two daily. The third case was not of above four or five months' duration. This patient was much reduced in flesh; I only saw him twice. He had long been afflicted with rheumatism and chronic dyspepsia. The gentleman in whom the fourth case, above referred to, presented itself, tells me that though worried by the disorder for four or five years, it produced no ill effect on his bodily health.

The pulse is not at all affected; the appetite is, generally speaking, good, and the tongue remains clean; pressure is not productive of pain in any part of the abdomen. I never found any tenderness in the ileo-cæcal region. The evacuations, though liquid, look healthy;

they generally consist of broken down fæces, intermixed with rounlish soft lumps. In neither of the two cases which I examined minutely could I detect any thing abnormal in the rectum. There were no hæmorrhoidal tumors in either, and no increased irritability of the lining membrane. In fact, in none of the cases I have witnessed, was there reason to believe that the rectum was at fault, inasmuch as the motions were in all voided without pain, and without tenesmus. All the individuals were males, of sober habits, and past the middle period of life. Two of my cases recovered; the third I lost sight of. One attributed, and apparently with good reason, his illness to scarlet fever, from which he had scarcely recovered when the bowel complaint made its appearance. In none of the others could it be traced to any particular cause.

I am at a loss to say what part of the intestinal canal is affected, in this form of diarrhœa, or in what the precise nature of the affection consists. As the general health seems to retain its vigour—the assimilative process, it would appear, is unimpaired—we may therefore infer, that the termination of the colon is the seat of the disorder, and this probably consists in a limited patch of inflamed mucous membrane, or in inflammation of one or other of the subjacent textures. I was at first disposed to attribute the symptoms to an irritable state of the rectum; and not until I had satisfied myself by repeated examinations both by the finger and bougie, and watched the effect of local treatment, did I arrive at a contrary opinion.

My experience in the treatment of this form of diarrhœa is but limited. I have, however, seen enough of it to convince me that it is exceedingly untractable. One case, after having been six months under the care of various practitioners, and taken the usual remedies for chronic diarrhœa, was subsequently, for a similar period, under my observation, before any impression appeared to be made on the complaint. At length remedies which had previously failed now proved beneficial, and he gradually recovered. Another case was for upwards of nine months under my care. Almost every thing that gave promise

of a hope was tried in this case, both as regards diet, regimen, baths, and medicine. The means adopted, if at all operative, appeared to be beneficial temporarily. At last the complaint gave way, and was ultimately cured by a tour in Scotland.

The remedies which I had recourse to in these cases were the various mineral astringents recommended in chronic diarrhœa, with larger or smaller quantities of opium, and in various combinations and doses. Not one or any of these appeared to do good; and the disorder was increased on one or two occasions by the sulphate of copper and by the acetate of lead, these substances seemingly adding to the irritability. I have always derived more benefit in this disorder from the vegetable astringents; and a mixture, consisting of the infusion of cascarrilla, the liquor potassæ, and the compound powder of kino, has been most generally useful. Were I to attribute recovery to any one means, I should say in two of the cases it was owing to this mixture. Whenever I succeeded in keeping the individuals on a limited allowance of food, there was generally an obvious improvement, and quantity seemed to have as much effect as quality in restraining the disorder.

I cannot aver whether a vegetable or animal diet is best suited to these cases. From what I have observed, however, I should rather lean to the former; but, as regards diet, the smaller the quantity taken, the less troublesome will the complaint be found.

I may remark that, in the case of recovery, after being afflicted for four or five years, the individual at length recovered by restricting himself solely to a vegetable diet, consisting principally, he informs me, of greens and cabbage. This gentleman had been a patient of almost every physician of reputation in London, without deriving permanent benefit from the means employed, when, tired of medicine, "finding that he *must have* three or four motions before breakfast," he discontinued taking any, and speedily recovered under the system which he had himself adopted.

I have thrown out these few observations on this obstinate form of diarrhœa, more with a view to inquiry than the expectation of elucidating the

subject; and if I succeed in bringing it to the notice of any one of experience, I shall have gained a main object in communicating them to the public.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicee* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

THE LATE REPORTS ON PRISONS.

It is obvious that imprisonment may be conducted on two opposite systems. In the one, the object is to inflict the utmost possible pain, and inspire the utmost possible terror; in the other, it is thought right that the punishment should bear some proportion to the offence, while the reformation of the criminal also enters as an element into the calculation. The first or old system was very simple, and as long as justice and humanity slumbered, was singularly easy of execution. Put a prisoner into a cell, chain him for security, flog him if he makes a noise, give him a minimum of food, and no materials for washing, and the problem is solved. But, it will be answered, this is an exaggerated and impossible series of suppositions. Not very exaggerated, it may be affirmed, if we recede from the present scene to some distance in time or space.

Esquirol speaks of towns in France, where, in *his own time*, prisoners and lunatics alike had but a three-pound loaf and a jug of water, every other day, for their subsistence*.

But if we go back to the reign of Queen Elizabeth, and look with the eyes of history on the cells of "little ease," in which she immured some of her state-prisoners, the description we

* Sur les Maladies Mentales, vol. ii. p. 410.

gave above will appear all too favourable. Her cells, if we recollect aright, were below the level of the Thames, were infested by rats, and did not allow of the prisoner's lying-down. No humanity-mongers had troubled the eternal peace of those quiet dungeons! Those were the days of "rotting in jail," as our ancestors termed it. If a prisoner escaped with his life from those dank and dreary receptacles, if his gaunt form and matted locks were seen in the broad daylight, and he could shew his fellow-citizens his back marked with stripes, and his joints stretched by the rack,—surely this would produce the most hushed and passive obedience among his affrighted comrades? By no means. When punishment is utterly out of proportion to crime, indignation overpowers terror, and a state of opinion is excited, which every wise legislator would deprecate, a state where sympathy is not with the law, but the offender. If punishment is over rigorous, its continuance calls forth the pity of the just, and they are ready to say of the criminal,

Il est assez puni par le sort rigoureux
Et c'est d'être innocent, que d'être malheureux!

When our statute-book emulated the code of Draco, and two hundred offences were capital, juries used to value a gold watch at 39 shillings. The ease, however, with which the old system was executed, by no means became the inheritance of the new. The plan of graduated punishment and attempted reform is evidently a just medium most difficult to hit,—a system of compromises very difficult to defend. If the diet, for instance, of a prison is too low, scurvy and diarrhoea are the result; add some meat and greens to the dietary, and many will exclaim that criminals in the House of Correction live better than the ploughmen without. Opinions on the subject of whipping vary most strangely, as we showed in

our last article, in different parts of England. Solitary confinement, the other great resource in the government of a prison, if pushed beyond the proper limit, induces madness or suicide; and who has ascertained the "proper limit," who has fathomed the hallucination, which are the precursors of madness, or gauged the depths of human endurance?

Nay, even a subject apparently so plain as the education of the inmates of a jail, is not without its difficulties and dangers. It has been objected that a prison is made too agreeable by turning it into a school; and it is feared that some persons will commit petty offences, with the hope of receiving a gratuitous education, and having their reading made easy*.

Another difficulty has sprung up, which we should not have expected to exist to so great an extent as it does. Not only the well-known intentions, but the plainest enactments of the legislature, are constantly and unblushingly violated by the visiting justices, whose office it should be to execute the minutest injunctions of the law. The instances of this dereliction of duty are lamentably frequent in the Reports before us. In a very singular example occurring at Canterbury, the blame must be at least shared by the Town Council.

The visiting justices recommended to the Town Council the appointment of a clergyman of the Church of England as chaplain to the City Jail, with a salary of fifty pounds a-year. "A

* A new method of making reading easy has been discovered, as we learn from Mr. Hill in his Report on the Prisons of Scotland. "Instead of a wearisome expenditure of time in alphabets and unmeaning combinations of letters and words, the most intelligent teachers in the prisons commence at once by teaching the prisoner to decipher a simple phrase of a simple and interesting story, by telling him the words one after another, as if they were so many pictures, and going over the ground again and again until his [their] pupil is thoroughly master of what has been put before him." Is this novelty an improvement? We know not; *judicent peritiores*, as the critics say.

moderate stipend, indeed," the reader will say. Not so the Town Council. They fancied twenty-five pounds to be the fitting sum, but no one would take the place. Mr. Walker, however, the minister of a Unitarian congregation in Canterbury, attends the prison gratuitously. He goes through the service of the Church of England, omitting those parts which he cannot conscientiously read; preaches sermons, in which he avoids everything relating to his own peculiar tenets; and teaches the prisoners to read and write. The inspectors, while acknowledging the merits of Mr. Walker, point out to the magistrates the extreme illegality of their economic plan. Four different enactments of two modern statutes are violated by the appointment of a dissenting minister to the chaplaincy of a prison.

If the Town Council are inaccessible to reason, surely there must be some legal method of forcing them into decency. Would not the Court of Queen's Bench grant a mandamus to compel them to offer a proper salary?

That the keeper of a jail should live in the prison which he professes to keep, seems a self-evident truth—too plain to need the sanction of an Act of Parliament. Yet, strangely enough, it is so stated in the law; and, still more strange to say, the enactment is violated in several English jails.

What is to be done with juvenile offenders, with young thieves, say under 18 years of age? A question of much importance, and most difficult of solution. It is allowed on all hands that the commitment of young delinquents to jails, where they associate with hardened criminals, is in the highest degree cruel and inexpedient. Society loses more by this contamination of the young, than it gains by their chastisement. Either our prisons must afford the means of isolation for the young, or there must be separate asylums for their use.

"It was with pain," say the inspectors, when speaking of the Ilford House of Correction, "we found several boys in the prison, three of whom were committed for absconding from the union workhouse. They were in a yard in which were prisoners convicted of theft. The close contact in which they were placed with worse characters than themselves could not fail to be mischievous, and the workhouse or vagrant boy would thus readily become converted into a thief. We strongly doubt the policy of sending to a jail juvenile offenders for breaches of workhouse discipline*."

We cannot, however, agree with those who, to avoid the contamination to which untried prisoners are exposed, would deprive juvenile offenders of the benefit of trial by jury, and make summary conviction the almost universal rule in their case. Let jail deliveries be more frequent, but do not give up a large portion of the population to the caprice of county justices.

As for tiny transgressors, aged 8, or 9, or 10, we think the old domestic remedy of spanking the glutæi more appropriate than incarceration in the most exemplary penitentiaries. In the borough of Kingston-upon-Hull, however, a very different theory prevailed, and *unconvicted* children were habitually sent to jail, with the consent of their parents, to expiate their offences. The following is one of the *lettres-de-cachet* used in this borough:—

"To the Governors of the Gaol at the Borough of Kingston-upon-Hull—

"Receive A. A., and keep him in solitary confinement for 14 days; this is done with the consent of his parents. This boy is to be well flogged before his discharge, twice.

*"Dated the 29th day of September, 1841.
"B. W. Sellon†."*

This culprit, as early in years as in initials, was of the age of ten!

The list of the young people com-

* Sixth Report. Home District.

† Seventh Report. Yorkshire, East Riding.

mitted in this way to Kingston-upon-Hull jail by justice-made law, in 1840 and 1841, amounts to fifty-seven; of whom three are aged 9; seven are aged 10; seven, 11; and only one is so old as 17. One child, aged 11, is to be kept in confinement one calendar month, the last week solitary. This monstrous abuse of authority was not always committed with the consent of the parents; for in one instance we find "no consent specified;" in another (a child of 12), "*done with the consent of the relieving officer of the parish of Sculcoates.*"

Captain Williams, the Inspector, having previously recommended, but in vain, the disuse of this "extraordinary treatment of children," made a special report on the matter to Sir James Graham, who ordered the practice to be discontinued.

The justices of Kingston-upon-Hull have hitherto been deaf to law, common sense, and the admonition of the inspector; the next Report will inform us whether they have listened to a Secretary of State. But though Kingston-upon-Hull appears to stand alone in the punishment of unconvicted children, convicted offenders of very tender years are common enough in other places. Thus, in the same Report, we find an account of the House of Correction at Cockermonth, where two prisoners were sentenced, in 1841, to pass twenty-four hours, for damaging a quantity of stones; one of the transgressors was aged 7, the other 9! In the same jail, too, was a child of 12, committed for seven days, for being disorderly in the workhouse.

In his account of the House of Correction at Nottingham, Capt. Williams says, "I am very doubtful as to the treadwheel being either a proper or a salutary punishment for children. *I observed two boys, each 10 years of age, on the wheel at the time of my visit.*"

Instances of precocious imprisonment abound in the Sixth Report. Thus, at Abingdon, in the County House of Correction, we find a child of 13 condemned to a month's imprisonment with hard labour, for stealing potatoes; and one of 14 for three months, with hard labour, for running away from the workhouse; a fault, we should say,

Ignoscenda quidem, scirent si ignoscere
Manes!

In the same place, among the list of those punished for breaches of prison discipline, we find a convicted child of 13 sentenced to a day's solitary confinement for talking, and an unconvicted one of 14 to three days' solitary confinement for whistling and singing: while two offenders of 12 and 14 are condemned to live for three days on bread and water, the former for being disorderly in his cell, the latter for the same defect in school.

In the Aylesbury County Jail we read of a youthful malefactor of 12, sentenced to a month's hard labour for damaging a pair of spectacles; while one of 15 has thrice his punishment, and another of 15 has four times as much; the former for stealing apricots, the latter for damaging fir-trees. In the same prison is a child of 13, sentenced to seven years [transportation] for stealing money.

In the St. Alban's Liberty Jail and House of Correction we find a prisoner aged 13 confined for two months, with labour, for stealing apples; and in the County Jail at Canterbury, a child of 11 sentenced to ten years' transportation, for breaking into, and stealing in, a dwelling-house. Among the prison offences punished in the same place, we find one of neglecting his work, and talking, ascribed to a delinquent aged 9, the penalty being "two days' dark cell." Two prisoners, aged 15, expiate the error of talking or being disorderly

on the wheel, by seclusion in the dark cells.

In the City Jail of the same town the attempted escape of E. P., aged 12, is avenged by twenty-four hours' solitary confinement.

In the list of punishments for breaches of discipline in the Dover Borough Jail, so many of the culprits are 12, 13, 14, or 15 years of age, that one might imagine the prison to be a kind of austere nursery. Nay, J. C., æt. ten, appears thrice in the list, once for indecent language, once for neglecting his work, and once for neglecting his lesson, the chastisement in each case being solitary confinement.

In the Clerkenwell New Prison we find several children aged 9.

Would not the domestic remedy which we extolled above be applicable in many of these cases? However this may be, we must repeat that a classification of prisoners is one of the most crying wants of the age. In the Springfield County Jail for Essex, the inspectors found a man convicted of bestiality in the same yard with prisoners guilty of trifling thefts, damaging grass, and furious driving!

Let us hope that the servant-girl committed to Northleach Jail, a short time since, for modesty, has not been compelled to herd with prisoners reproachable with a contrary defect.

FELLOWES' CLINICAL PRIZE REPORTS.

By ALFRED J. TAPSON.

University College Hospital. 1842.

CASE I.—*Acute pneumonia, affecting the lower lobe of the left lung chiefly, extending a little into the right lung, with fever, pain, dyspnoea, cough, rusty expectoration, dullness on percussion, bronchial respiration, crepitation, bronchophony, diminished vocal fremitus, &c.; complicated with incipient phthisis. Treated by cupping and tartar emetic, &c.*

Edwin Brown, æt. 17, admitted into University College Hospital, under Dr. Taylor, June 21st, 1842.

A youth of rather slender conformation, fair complexion, and nervous temperament; an errand-boy, exposed to all kinds of weather: has always had enough to eat; says his habits are temperate. Lives at Eagle Street, Holborn, in a dry but confined situation. Parents both living; mother troubled occasionally with catarrh, and father generally has a cough in the winter, and frequently has rheumatism: has six brothers and sisters; one of the latter has usually a cough; the rest are healthy.

Previous history.—He has never been laid up with a severe illness, but his health is habitually delicate; takes cold very easily; his breathing is generally short, and he is subject to palpitation. About three years since he spat a small quantity of blood, with coughing, and has had more or less cough ever since, especially in the morning, and it has been increased for some months past; has been losing flesh during the last two or three months, and for a month past has sweated considerably at night. He had gonorrhoea and chancres a year ago, and was cured by taking mercury. The present attack commenced on June 18th; on the 17th, he had been engaged in chopping wood in a draught between two doors, and was heated a good deal with his work; he was not exposed to wet. The attack came on pretty suddenly, with an aching pain in the left side, which prevented him from breathing freely, the pain being rendered very sharp when he took a full breath; it was not preceded by shivering, or other symptoms of fever, except about a fortnight before the attack, when he had a cold; he also had pain in the head, back, and limbs; great heat of skin, thirst, anorexia, weakness, with shortness of breathing; a dry, hacking cough, accompanied with difficult expectoration of a white, very "sticky" matter. In the afternoon this became yellowish, and the next day brownish; he vomited a considerable quantity of a bitter yellowish matter on the evening after the attack commenced, and the vomiting has returned after eating or drinking till to-day. The bowels have not been opened since the attack till this morning; the urine has been scanty, but not high coloured.

[We this week present our readers with the first of a series of reports of medical cases reported and commented upon by Mr. Alfred J. Tapson, and which form a part of the exercises for which the Fellowes' Clinical Gold Medal was awarded at University College Hospital at the termination of the summer session of 1842. The reports will be slightly abbreviated, &c., to render them more adapted for general circulation.]

At present, the surface feels very hot and dry; the temperature in the axilla is rather above 106° Fah.; the countenance is strikingly dull and heavy, and of a dusky colour; the senses seem to be blunted; he is rather deaf, and seems very weak; he lies chiefly on the left side, because he feels easiest in that position. The breathing is short and very quick, and almost wholly costal; the respirations 48 in a minute: he has a hard, frequent cough, with rusty-coloured, very viscid expectoration, so that the vessel containing it may be inverted without its running out. The cough is not quite so bad as it has been, and the expectoration is rather more free: he complains of a severe pain in the left side, just below the lower angle of the scapula, and there is some tenderness on firm or even slight pressure here; the pulse is 128, jerking, moderately full, not hard; the tongue is very dry, and is covered with a coarse, brownish fur; he is very thirsty, and has no appetite.

Physical signs.—Posteriorly, there is perfect dulness on percussion over the lower two-thirds of the left lung, as compared with the right, where the sound is clear, except in the region of the liver. In the same parts as the dulness on the left side there is well-marked bronchial respiration, and strong bronchophony; and at the lower angle of the left scapula the voice has a somewhat nasal twang, not amounting to ægophony. At the end of inspiration, crepitation is heard in the same situation; on the right side, there is bronchial respiration at the base of the scapula, and a slight muco-crepitant rhonchus; the vocal fremitus is felt much more distinctly on the right than on the left side. Anteriorly, there is no dulness on percussion; the respiratory murmur is rather feeble in the lower part of the left side, and rather puerile in the upper part; it is more puerile all over the right side; the vocal fremitus is more marked on the right than on the left side. The heart's sounds and impulse are rather feeble; no morbid sound.

Cucurb. Cruent. lateri sinistro, ad. f3x.

℞ Calomelanos, gr. v.; Miceæ panis, q. s. fiat pilula statim sumenda et post horas quatuor Haust. Sennæ Comp.

℞ Antim. Potassio. Tart. gr. j.; Misturæ Camphoræ. f3iss.; ft. Haustus, sextiss horis sumend. Low Diet.

Three hours after the cupping he felt much easier; the skin was cooler; and the respirations only 36 in a minute. The blood contained more coagulum and less serum than usual.

June 22d.—Countenance much less heavy; face not flushed; has slept nearly all the night; skin much cooler (the temperature in the axilla being 98° Fah.) and perspiring freely; the breathing much slower, and

rather less costal; no apparent difference between the two sides; respirations only 28 in a minute; cough diminished; expectoration more free and less viscid, not uniformly rusty, and is more yellow, like orange marmalade, than the reddish brown of pneumonia in general; pain much easier; tongue moister, red at the apex, and furred in the centre; no crepitation heard to-day; pulse 88, soft and compressible, scarcely jerking. The bowels have been opened freely three times: the urine is very scanty, only half a pint having been passed since his admission: its reaction is very acid; sp. gr. 1026; it is turbid, with a yellow sandy matter in it, which is dissolved by heat or nitric acid.

Sumat. Haust. Antimonial, omni 4tâ. horâ.

24th.—Did not sleep so well; perspired less; had more pain in the left side, and also in the back, and more cough; is rather hoarse, and his head feels rather stuffed, as if he had taken cold; surface of the natural temperature; respirations 24 in a minute; pulse 80, smaller and soft; expectoration about the same in quantity, but of a more mixed character, partly rusty, partly streaked red with blood, partly frothy, and contains some little opaque yellow masses floating in it: it is much less viscid: thirst less; the tongue feels sore, only slightly furred along the middle; urine increased in quantity, tolerably clear.

Physical signs.—Posteriorly, on the left side, percussion is still dull in the lower part, and in the middle third the respiration is strongly bronchial; below, there is more vesicular murmur heard, and a muco-crepitant rhonchus, with the inspiration, and bronchophony; on the right side the percussion is rather dull in the middle third; the bronchial respiration is more marked, and there is a rather acute muco-crepitant rhonchus. The vocal vibration is more nearly equal on the two sides, but still is most distinctly felt on the right side.

25th.—Better in most respects; but the tongue is much more sore, and is very dry, and chapped along the middle; the abdomen feels tense and rather enlarged; the bowels have not been opened since the 23d, and he has made no water since yesterday morning.

Repet. Pilula Calomel. et Haust. Purgans.

Soon after this, the bowels were freely opened, and he passed plenty of water.

27th.—Is much better altogether: still has a little pain and soreness on the left side when he coughs, or draws a deep breath; the cough and expectoration are both getting less; the expectoration consists chiefly of clear mucus; the respirations are 23 in a minute; the pulse 80, soft, compressible, and regular. The dulness, on percussion, on the left side is much diminished, and the

pulmonary resonance increased; the respiration is still rather bronchial in the middle third, and feeble in the lower third; no crepitation anywhere; and only a coarse mucous or muco-crepitant rhonchus with the cough.

Sumat. Antim. Potassio Tart. gr. $\frac{1}{2}$,
tantum pro dosi.

July 1st.—Still has a slight pain on coughing; the cough and expectoration much the same as at last report; tongue still rather sore and red; appetite returning; percussion still rather dull in the lower part of the left side, and slightly so on the right also; and the respiration partakes of a bronchial character in both, but is mixed with more vesicular murmur; a coarse muco-crepitant rhonchus is heard when he coughs; urine increased in quantity, of a lighter colour, and sp. gr. 1011.

Omit. Haust. Antimonial. Ordered a pint of milk in addition to low diet.

July 2d.—Improving; muco-crepitant rhonchus heard nearly all over the left side behind.

℞ Potassii Iodidi, gr. iij. Mist. Camphoræ,
℥iiss. ter die sumendus.

July 4th.—Breath still short; cough and expectoration less; the expectoration is chiefly mucous, with a few flakes of opaque matter floating in it.

Augê Potassii Iodidi ad gr. v. pro dosi.

July 6th.—Very much better in every respect; feels stronger; has scarcely any pain left; appetite good; tongue clean; bowels regular; urine free, clear and natural. Vesicular murmur increased on the left side, and not much bronchial respiration on either side.

Ordered middle diet, and two pints of milk daily.

July 9th.—He does not gain strength so rapidly as, from the improvement in the disease, he should do: this led to a more particular examination of the upper part of the chest, to see if there was anything there which would explain it; we found that percussion was not clear in either of the supra-scapular fossæ, and of the two the right was rather the duller: under the clavicles the sound was not near so clear as it ought to have been, from the thinness of the walls of the chest, and here too the dullness was most marked on the right side; the respiratory murmur was "rude" under both clavicles, and under the right the expiration was prolonged; the vocal fremitus was considerably greater on the right side than on the left. Both moved equally in inspiration.

July 11th.—Is tolerably well, but feels weak; has no pain left; the cough is considerable, and the expectoration very little

and consists of clear mucus; there is scarcely any difference in percussion on the two sides below and behind; no bronchial respiration in either; the vesicular murmur is still a little feebler on the left than on the right side.

Discharged cured.

REMARKS.—The diagnosis of the disease was exceedingly clear. 1st. from his appearance: the countenance had that peculiar heavy and dull, yet anxious expression, and purplish flush, which characterise pneumonia. 2d. from the mode of attack, which was in almost every respect that of pneumonia, viz. a sudden attack of pain in the side, causing dyspnoea; depression, head-ache, pain in the back, and when reaction commenced, a hot and dry skin; thirst; cough and viscid expectoration; anorexia and vomiting. One symptom which is generally present was absent, viz. the premonitory attack of feverishness; a shivering fit followed by heat, before the recurrence of any local symptoms. Chomel attaches great importance to this symptom, especially in persons advanced in life, believing that it not only generally precedes pneumonia, but also that the occurrence of a severe rigor almost always indicates the approach of pneumonia. 3d. from the symptoms and signs which existed on his admission to the hospital, which was on the 4th day of the attack. Of the general symptoms the following were the more important. (1.) the countenance, already noticed, with which may be classed the dullness of the senses and the position on the affected side. (2.) the great heat, and the dryness of the skin. (3.) the short and quick respiration. (4.) the quick and jerking pulse. (5.) the severe pain in the side, and tenderness on pressure. (6.) the hard and frequent cough, and viscid rusty coloured expectoration.

Of the physical signs the following were the chief. (1.) the costal respiration. (2.) the dullness on percussion in the lower two-thirds of the left lung posteriorly. (3.) the well-marked bronchial respiration and bronchophony heard in the same situation. (4.) the crepitation at the end of the inspiration. (5.) the diminished vocal fremitus on the diseased side.

With all these there could be no doubt as to the nature of the disease: indeed, the crepitation and rusty coloured viscid expectoration, by themselves are pathognomonic of pneumonia, and when to these we add the general fever and signs of consolidation, not the slightest doubt could remain.

We shall now make a few remarks on some of the symptoms and signs. And first with respect to the heat of the skin. In the limited number of cases in which we have actually measured the temperature, it appears to be uniformly high in the active stage of pneumonia: in this case it was 106° F., and in two others

104°. Secondly, as to the frequency of respirations. This also appears to be much increased; in this case it was 48 in a minute; in another which will be reported, it was 54, in a third 44, and in a fourth 36. This sign alone is not of much diagnostic value, as we have counted 72 respirations in a minute, in a case of hysteria: thirdly, the pulse has been very rapid in several cases; in this it was 128, in another 148, and in two others 120. Now these three symptoms appear to be very closely connected in pneumonia, for in all the cases, where we have particularly marked them, the decline has been proportional in each: thus, in the present case, on the first day the pulse was 128, the temperature of the skin 106° Fahr., and the respirations 48 in a minute; on the second day the pulse was 88, the temperature 98° Fahr., and the respirations 22—all reduced nearly to the natural standard except the respirations, which were habitually frequent in him: in another case, on the first day the pulse was 148, the respirations 54, and the temperature 104°; on the second day the pulse was 120, the respirations 36; on the third day the pulse was 112, and the respiration 32; and on the sixth day both were about the natural standard, viz. the pulse 80, and the respirations 20 in a minute, and the temperature was 99° Fahr. We can easily understand this intimate connection between them, when we consider the very close connection that subsists between the functions of circulation, respiration, and the production of animal heat. Fourthly; as to the position of the patient in pneumonia, there seems to be no constant rule: taking all the cases together, perhaps he as frequently lies on the back as on either side: if the attack be mild he often lies on the non-affected side, but if it be severe, and limited chiefly to one side, he almost always lies on the affected side, as here, both to prevent motion on that side, which would increase the pain, and also to permit free motion on the healthy side, so that it may perform the supplementary respiration as completely as possible. Fifthly; as to the vocal fremitus. This, we have seen, was modified by both the diseases which existed being increased by the tubercles and diminished by the pneumonia. The vocal fremitus depends on the vibrations which are produced in the vocal chords being propagated along the columns of air contained in the trachea and bronchial tubes, and transmitted from the smaller bronchi and air cells through the substance of the lungs and parietes of the chest, so as to be felt by the hand, when applied to the exterior of the chest. Like the voice itself, these become diminished as they pass from the place where they are produced, either into the external air, or into the air contained with-

in the lungs, and consequently they are felt most distinctly over the large bronchi; as may be proved by placing the hand over the upper part of the sternum, and then over the lower parts of the chest, during the act of speaking: they will be felt much the most distinctly in the former situation: this will shew the necessity of always comparing corresponding parts of the chest in this as well as in other physical signs. Such being the mode of production and natural variations in the vocal fremitus, we have to consider how it is modified by disease, and any explanation that may be offered must obviously be based on the physical conditions of the lungs, as its whole production is a physical phenomenon.

It is clear that since the vocal fremitus depends on the vibration of the air, anything that excludes the air from the lungs will prevent the vocal fremitus. We saw one case in the hospital, where the large bronchus leading to the right lung was very much pressed upon, and the texture of the lung itself condensed by carcinomatous depositions, and in this there was a complete absence of the vocal fremitus.

The vocal fremitus has by some writers been stated to be increased, and by others to be diminished, by condensation of the texture of the lung; and this case seems to shew that both statements may be correct; for in the upper part of the right lung there were the other signs of condensation, and from the general symptoms this condensation was due to the presence of tubercles; also, in several other well-marked cases of incipient phthisis, in the hospital, under Dr. Taylor, the vocal vibration has been found to be distinctly increased on the side most affected; and in the lower part of the left lung it was much diminished, as we have also seen in other cases. Now both tubercles and pneumonia cause consolidation of the tissue of the lungs, and unless there be anything in the physical nature of the consolidating material, or in its mode of deposition, to cause a difference, both should increase or both diminish the vocal fremitus; and such, we have seen, is not the case: is there any difference in the material, and what is the difference, if any? In tubercles the material is dense and hard, and is deposited in the tissue, rendering it harder and more capable of vibrating, and at the same time it does not block up the small bronchial tubes, so that the air still comes pretty close to the surface of the lung. Combining the last fact with the increased capability of vibration in the tissue itself, we can explain the absolute increase in the vocal fremitus in the early stage of tubercles. On the other hand, in pneumonia the consolidating material is soft lymph, devoid of elasticity, and this is deposited in the tissue and also in the air cells and smaller bronchial

tubes, thus more or less completely excluding the air from the diseased part of the lung; so that the vibrations, in order to reach the surface of the chest, have to be conducted through a much greater mass of tissue than in health, and therefore, unless the tissue becomes correspondingly more capable of transmitting the vibrations, the vocal fremitus must be diminished. That there is no such increased vibratile capability must be evident when we consider the soft inelastic character of the lymph; for vibrations cannot well take place without a certain amount of tension and elasticity; and we think that the fact of the air being prevented from coming so near to the surface of the chest, as it does in health, and the nature of the consolidating material, taken together, are quite sufficient to account for the absolute diminution of the vocal fremitus in hepatization, as well as the relative difference between this and the consolidation of incipient phthisis.

But it appears that, in some cases of pneumonia, the vocal fremitus is increased rather than diminished: how can we reconcile these facts? It may be, perhaps, that in the cases where this has been noticed, the inflammation was seated in a part where there are a number of tolerably large bronchial tubes near the surface of the lung, such as would not be blocked up in pneumonia, and the lymph itself has been more highly vitalized and firmer; and then the consolidation of the air-cells and very fine tubes may rather favour than impede the transmission of the vibrations: or it may have been examined at an earlier stage of the inflammation, before the hepatization was complete, and when, therefore, the tubes were less obstructed, and when, also, as is well known, the lymph effused is more plastic, and possesses a greater amount of cohesion.

Having thus proved the disease to be pneumonia, what were the *indications for treatment*? This we shall consider in connection with the results of the treatment adopted. As in almost all acute inflammations, so here, blood-letting was to be regarded as the primary step to be taken; and perhaps in no disease is the advantage of blood-letting so immediate and so great (when practised early) as in pneumonia. Blood-letting being indicated, the next point to be determined was, whether it should be performed generally or locally, or both, and to what extent? The patient was young, and of a weakly appearance, and the disease had already existed four days, and was on the point of passing into the second stage; it was not therefore to be cut short by a full blood-letting: accordingly it was considered that local blood-letting by cupping to ten

ounces would be sufficient. This was immediately done, and the good effects were almost instantly apparent: the pain was relieved directly, and in three hours the respirations were reduced from 48 to 36 in a minute; the skin was much cooler, and the pulse reduced in frequency and force. These are symptoms much to be depended on in ascertaining the decline of this disease. As the bowels were confined, the next thing to be done was to clear these out: this was done by a dose of calomel and a black draught; and he was ordered tartar emetic, in grain doses, every six hours at first, and then every four hours. This is the medicine commonly used in inflammation of the parenchyma and mucous membrane of the lungs, and in both its operation is highly satisfactory: how it acts we do not pretend to say. The next day the general aspect of the patient was much improved: he had slept well; the skin was of the natural temperature, and instead of being harsh and dry, was covered with perspiration; the pulse was only 88, and soft; the breathing had been reduced, in eighteen hours, from 48 to 28 respirations in a minute. The physical signs were also closely examined, and were found to be somewhat altered; that is to say, there was no crepitation; so that the disease had now completely passed into the second stage, or that of hepatization, the signs of which were well marked. In other respects they were much the same as on the first day, and have therefore been omitted, in order to render the account as short as possible consistently with a statement of all the facts. The expectoration was now more free, less viscid, and of a paler brown or marmalade colour, and more frothy; gradually the rusty tint passed off, and the blood became less intimately mixed with the expectoration; so that it appeared in streaks, and then ceased altogether, and the expectoration became almost simple mucus, with a few opaque masses. In accordance with the usual law, that when the respiration is prevented in one part of a lung, or in the whole of one lung, the other parts have an increased duty to perform, we found that, in front, in the upper part of the diseased side, the respiration was puerile, and on the healthy side it was puerile all over.

The inflammation, which at first was almost limited to the left side, gradually extended into the middle lobe of the right lung, and on the 24th, in this part, there was dulness on percussion, well-marked bronchial respiration, and a pretty acute muco-crepitant rhonchus, and the vocal fremitus, though still more distinct on the right side, was more nearly equal in the two. There was a double cause for this; for the disease was diminishing on the left side, as indicated

by there being some vesicular murmur heard and muco-crepitant rhonchus, and it was increasing on the right side. Thus the disease was now double pneumonia: and this is the way in which double pneumonia almost always arises, viz. by extension from one lung to the other, except in those cases where it arises from congestion converted into inflammation by the occurrence of reaction, as in typhoid pneumonia, and in old subjects, in whom it is generally fatal. With this extension of the disease there was a slight increase of the general symptoms: the rest was disturbed, the skin was drier, and the cough more troublesome, &c. But this secondary inflammation was of short duration, and disappeared before that on the left side; so that it did not materially affect the interests of the patient.

He continued gradually to improve, and the dose of tartar emetic was diminished, and then left off altogether, the diet improved, and iodide of potassium given, with the view of removing the remains of the inflammation and promoting the absorption of the effused lymph; and on the 11th of July he was discharged cured.

The *duration of the disease*, reckoning from the time of his admission to the time of his discharge, was twenty days; or reckoning from the time of the attack to the time at which he was allowed better diet, it was nineteen days. The duration was probably increased by the tubercles, which, we believe, existed in the lungs, and which always operate strongly in retarding the recovery from pneumonia. Had the patient's health been good previously, he would have shown more elasticity, and regained his strength more rapidly.

Were there any *complications*? The most common are pleurisy and bronchitis; the former is stated by the French to be a constant accompaniment of pneumonia, and no doubt is very frequently. In this case there was no decisive evidence of its existence at any period of the disease; the slightly nasal twang which the voice had at one spot cannot alone be taken as sufficient evidence. There was probably bronchitis, but not enough to interfere with the progress of the pneumonia. Regarding the tubercles as a complication, we shall here notice the evidence of their existence. First, it is probable that he was predisposed to phthisis; his father and mother both being liable to affections of the chest, and one of his sisters usually having a cough. Secondly, his health was habitually delicate, he easily taking cold, and then having a cough; his breath generally short; he spat blood three years since with a cough, and the cough has been troublesome during the last winter; he has been losing flesh for the last two or three years,

and for a month has had night sweats. Here we have most of the general symptoms of phthisis enumerated, and his appearance confirmed the suspicion of its existence. Thirdly, there were the physical signs of condensation of the upper portion of the lungs, as stated in the report of July 9th. Combining the above, we can have but little doubt of the existence of tubercles.

There were no very important changes in the urine. It was scanty at first, and on the fifth day of the disease deposited a sand-like sediment, consisting of the lithates: this deposit commonly occurs in pneumonia about this time. Subsequently it increased in quantity, especially after the administration of the iodide of potassium.

The *causes* of the pneumonia were probably—1, the predisposition to pulmonary affections; 2, the cold which he had a fortnight before the attack; and 3, the actual exciting cause was the working in such a current of air as he did the day preceding the attack. This exposure to cold for some time, when heated, is the most common cause of pneumonia.

The *prognosis* of pneumonia is generally favourable when it occurs in youthful subjects; but of course it will vary with the extent of the lungs affected, and also with the part of the lung: thus, pneumonia of both lungs is less favourable than when one lung only is affected; and that of the upper lobes is more fatal than that of the lower lobes—said by Louis to depend on the fact of the former occurring more frequently in old people. Here it affected the lower lobe chiefly of the left side, and afterwards a portion of the middle lobe of the right lung. The attack was tolerably severe, but still the prognosis was favourable as to the result, from the age of the patient; and we have seen that he went out cured, or at least in that state in which the lung would probably soon return to the condition it was in before the attack.

Respecting the phthisis, the prognosis is now much less favourable than it was before the attack of pneumonia; for, of all the causes which accelerate the progress of phthisis, pneumonia is the most powerful. We cannot therefore but fear, that this disease, although apparently leaving him in the same state that it found him in, has exercised a highly deleterious influence on the duration of his life.

[We beg to acknowledge that, in this case, as also in those which are to follow, we have freely availed ourselves of the reports, and also of the remarks in the clinical lectures of the physicians under whom the cases respectively occurred.]

DEVELOPMENT OF BONE.

From a Report of the Paris Academy of Sciences, Nov. 7, 1842.

M. FLOURENS read a paper on the Development of Bone. "I have hitherto," says he, "considered the internal periosteum only as the organ of the re-absorption of the bones. This periosteum, however, is also the organ of formation. I now place under the eyes of the Academy a series of pieces of bone, showing the successive formation of new bone in the interior of the old bone. In all these specimens the internal periosteum has been destroyed; in some cases in the whole extent of the bone, in others at a single point only. When the external periosteum has been destroyed in the whole extent of the bone, a new bone is formed in the whole of the interior of the medullary canal; and when the external periosteum has been destroyed at only one point, new bone is formed only at the corresponding point of the interior of the medullary canal. Two powers, therefore, concur in the formation of bone—the power of the external periosteum, and that of the internal periosteum. In the normal state the action of each keeps within its own limits: the external periosteum produces or repairs incessantly the external bone. In the ordinary state, therefore, there is a counterpoise of these powers. But if the internal periosteum be destroyed, the power of the external periosteum being alone in its action, is augmented, and produces an entirely new bone outside the old bone; and if, on the contrary, the external periosteum be destroyed, then the power of the internal periosteum being increased, and alone in its action, an entire new bone is immediately produced in the interior of the bone. The experiments which have already been communicated to you have shown that bones increase in size by successive layers interposed upon each other. The experiments which I am about to relate on this point are still more decisive. Duhamel bound round the tibia of a young pigeon some silver wire; at the end of some time the silver ring was covered with bone, and was within the medullary canal. My experiments were in imitation of those of Dubamel. I bound some platina wire round various long bones of several animals—dogs, rabbits, guinea-pigs, &c. The result was as follows:—The new bone, which did not exist when the platina ring was put on, grew over it; thus showing that bone is formed by external layers."

The specimens exhibited by M. Flourens prove that there was neither extension, nor rupture, nor rejunction of the osseous fibres on the level of the ring; but M. Flourens

being desirous of showing this more completely, adds, "At the same time that I placed this wire on a long bone of an animal I amputated the corresponding bone of the opposite side, and preserved it, as it was to serve as a point of comparison. The animal was then left to itself, and, at the end of a certain time, was killed. The result of these experiments confirmed my former conclusions, and proved that the bone does not distend, that it does not give way, and that the new bone is formed over the old bone. The experiment was performed on the tibia of a guinea-pig. The animal was fed for twelve days on the plant from which is obtained the dye called *garance* (madder). The animal being then killed, and the bone dissected, all the new bone was found to be red, and the old bone white. All the new bone was above the ring, and all the old bone was under it. The old bone was of the same diameter as that of the opposite side, which was amputated on the day when the wire was bound round the other bone. When two perforations are made in the bone of an animal, and it is allowed to exist for a certain time after the experiment, the interval between the two perforations remains the same, and yet the bone increases in length at its extremities and by terminal layers. The periosteum is reproduced by external layers. In the experiments above mentioned the wire ring was placed above the periosteum, and the old periosteum afterwards found under it."

INVERSION OF THE UTERUS.

D. HUMPHREYS STORER, M.D., reported to the Boston Society for Medical Improvement, April 11, 1842, the following case of inversion of the uterus.

He was called to a woman in labour. In ten or fifteen minutes there came two smart pains, and the child was born. In five minutes the placenta was thrown off. The cord was not touched, except to divide and remove the child. On putting his hand under the clothes, to take away, as he supposed, the placenta, he found that he had hold of the uterus with the placenta attached. He removed the placenta, put his fingers to the fundus of the uterus, and passed it up without the slightest difficulty. There was some flowing from the uterus where the placenta was detached, but not great, and none after it had passed up. The woman was very much prostrated, and for an hour appeared as if she was dying. She however revived, and the next morning was comfortable. This case proves that inversion may take place without the interference of the practitioner; for no traction whatever was

made upon the cord, which was of the usual length, and not encircling the child.

Drs. Dewees, Burns, and Gooch, in cases of inversion, advise when it can be accomplished, the return of the uterus before the removal of the placenta, on account of the dangerous hemorrhage which is otherwise liable to ensue. Dr. Bard recommends the previous removal of the placenta.

Dr. Storer followed in this case the practice of Dr. Bard, and the case with which the uterus was returned, and the happy convalescence thus far, she being as well to-day (the sixteenth day after delivery,) as she had been at the same period during any former pregnancy, proves the course to have been a judicious one. The placenta was very large, and he believed that had he made any attempt to return it, he would have met with difficulty, from its mere bulk. In a case of inverted uterus, related by Dr. Meigs, of Philadelphia, in his Practice of Midwifery, he was unable to return it with the placenta, and at the suggestion of Dr. James, the after-birth was removed from its attachment. Afterwards, with considerable difficulty, a reduction of the organ was effected.

The little blood which was lost after the placenta was removed, in the case reported by Dr. Storer, showed, he thought, that the great dread of uterine hemorrhage, which is felt by physicians from the removal of the placenta, even should no uterine contraction immediately occur, is not well founded. As soon as the placenta was detached, the hæmorrhage ceased, and although the uterus was so completely relaxed as to allow the hand to pass with perfect freedom, without the slightest muscular contraction being perceived, there was no bleeding.—*American Journ. of Med. Sciences.*

ON A VERY SIMPLE MEANS OF ARRESTING EPISTAXIS.

By DR. NEGRIER, of Angers.

THIS consists in nothing more than closing with the opposite hand the nostril from which the blood flows, while the arm of the same side is raised perpendicularly above the head. In every instance in which he has had recourse to this means during the past three years, M. Négrier has always found that it suspended the hæmorrhage: a fact of which he offers the following explanation.

When a person stands in the ordinary posture, with his arms hanging down, the force needed to propel the blood through his upper extremities is about half that which would be required if his arms were raised perpendicularly above his head. But

since the force which sends the blood through the carotid arteries is the same as that which causes it to circulate through the brachial arteries, and there is nothing in the mere position of the arms above the head to stimulate the heart to increased action, it is evident that a less vigorous circulation through the carotids must result from the increased force required to carry on the circulation through the upper extremities.—*Archives Générales de Médecine; and Brit. and For. Med. Review.*

ON THE

TRANSFORMATION OF CALOMEL INTO CORROSIVE SUBLIMATE,

UNDER THE INFLUENCE OF THE CHLORIDES OF THE ALKALIES.

By M. LEPAGE.

M. J. RIGHINI D'OLLEGIO, in a note relative to the action of steam on the protochloride of mercury, has given the result of some experiments which he undertook with the view of determining whether, as has been stated latterly, the protochloride of mercury is transformed into the perchloride under the influence of the chlorides of the alkalies, at the temperature of the human body.

The conclusions announced by this Italian chemist have been entirely corroborated by the repeated observations I have made on the same subject. The following are the results of my experiments:—

1st. Protochloride of mercury, perfectly free from perchloride, and mixed with an equal weight of hydrochlorate of ammonia, or of a chloride of an alkali, digested in distilled water at a temperature of from 100° to 104° Fahr. during twenty-four, thirty-six, and even forty-eight hours, does not change colour. The liquor, when filtered, has never indicated, by any reaction, the presence of even a trace of a mercurial salt.

Pigeons that were made to drink this liquor during several days in succession suffered no injury. There appeared to be no diminution in the original weight of the calomel.

2d. The same mixture, exposed to a temperature of from 120° to 140° Fahr. afforded a liquid which comported itself with reagents, and in its action on the animal economy, precisely the same as the last mentioned.

3d. Nevertheless, by continued boiling, and under the influence of a large excess of chlorine, the transformation does take place; but it is even then only partial.—*Journal de Chimie Médicale; and Pharmaceutical Journal.*

ADVANCED STAGE OF THE PUTREFACTION OF THE BRAIN,

WITHOUT ANY CORRESPONDING APPEAR-
ANCES IN THE REST OF THE BODY.

M. MILLET calls the attention of medical jurists to the facts of the following case. On the 29th of August, 1840, an individual (a patient of M. Leuret) labouring under dementia and general paralysis expired. The body was, a few hours thereafter, removed to a cool room and laid on a zinc table. Here it remained during forty-one hours, when the dissection commenced. The temperature was about 86° of Fahrenheit.

The dura mater was found strongly adhering in several places. After separating it, and opening into the brain, the cerebral mass of both hemispheres was seen converted into a yellowish-green fluid streaked with blood, of an offensive and penetrating odour. In the midst of this putrid mass, near the left corpus striatum, there was a portion more solid and resisting, evidently the result of a ruptured vessel (*un foyer apoplectique*.) It was surrounded by a number of whitish vesicles, which on being opened, discharged a brick-red matter.

When the cerebral mass was spread on the table, it was scarcely possible to distinguish any of the circumvolutions—so complete had been the progress of putrefaction. Indeed, the lower part of the brain was green, and more spotted than the upper. The cerebellum was also in a state of complete solution, and even the spinal marrow, on being traced, was in a similar condition, and of a gray colour passing to green.

On the other hand, the right lung was healthy, but engorged; the left lung bore the marks of effusion, with some recently formed membranes; the heart was flaccid and discoloured; *the stomach and intestines healthy*; the liver and spleen a little softened and enlarged; the muscles of the trunk and extremities firm and hard; and the external appearance as usual in a dead body, except that the skin of the superior extremities was slightly greenish.

M. Millet inquires, if the head of this individual had been separated from the body (as in a case of assassination), any medical jurist would have recognized their connection, or whether he would assign so short a period since death as two days?—*American Journ.*; and *Annales d'Hygiène*.

A PERFECT WET-NURSE.

In choosing a wet-nurse, how many rocks are to be avoided! We must consider her age, her constitution or temperament, her health, her

character, her morals, her habitation, her way of living, and the quantity and quality of her milk. Her age should be between 20 and 35; she should be of a good constitution, and rather plump; she must be habitually healthy, and exempt from every disease, without apparent deformity, dark rather than fair, and never red-haired; her mouth must be embellished with fine teeth, her gums firm, her breath sweet, her breasts of an average size, variegated with bluish veins, the areola rather high, and the nipple well pierced and of a proper length. A woman must be rejected whose skin is covered with eruptions, whose perspiration has a strong odour, or who is afflicted with leucorrhœa, swelled glands, &c.—Capuron, *Cours d'Accouchemens*, Sixième Edit.

CASE OF INTERMITTENT MADNESS.

It is related that there was a carpenter, who when at home was a sober workman, and was skilful in measuring wood, cutting, planing, and nailing it, or in building a house; and he used to talk and strike a bargain properly with his customers. Within his workshop, he was of sound mind; if, however, he went out to the market-place, to the bath, or on any other business, he first laid down his tools and groaned, and then shrugged up his shoulders; but when he had got out of sight of his family, away from his work and premises, he was quite maniacal; but if he went back immediately, he came to himself also; so that his understanding had the same limit as his homestead.—*Areteus on the Causes and Symptoms of Chronic Diseases*, Book I.

BILLS OF MORTALITY.

In the sixteenth century we have, "given in reward to the Clerk of Coleman Street, for often time bringing bills of the sickness in town, XII^d." (Gage's Hengrave, 205.) So that they served instead of newspapers.—*Fosbroke's Encycl. of Antiq.*

QUACKS IN THE OLDEN TIME.

ARTHUR DEE was summoned before the censors for much the same crime; he having hanged out a table, in which he exposed to sale several medicines, by which many diseases were said to be certainly cured. This crime was deemed such an intolerable cheat and imposture, that the Censors ordered him to appear with his remedies in order to the inflicting a due penalty upon him.—*Goodall's History of the College of Physicians*, 1684.

ACONITINE.

POGGENDORFF'S ANNALS.

THIS organic base was discovered by Hesse in the *Aconitum Napellus* L. In the herb it is combined with an acid, the nature of which is at present unknown.

For its preparation, the dry pungent leaves are digested with spirit of wine (best in a Real's press), and the concentrated tincture mixed with hydrate of lime. The aconitine then remains in solution in the alcoholic liquor. After being separated from the precipitate produced by filtration, the liquor is mixed with dilute sulphuric acid, which precipitates the whole of the lime in the form of gypsum. The spirit of wine is partly recovered by distillation, and the residue [an impure sulphate of aconitine] mixed with water. The rest of the alcohol contained therein is removed by gentle evaporation, and the impure aconitine precipitated by carbonate of potassa.

The precipitate being pressed between paper, is dissolved in spirit of wine, and its colour removed by animal charcoal, when the solution yields, on evaporation, pure aconitine. A further purification and removal of colour may be attained by dissolving it again in sulphuric acid, decomposing the sulphate with hydrate of lime, and extracting the aconitine from the precipitate by ether.

Pure aconitine crystallizes from dilute alcohol in white grains, or it remains behind, if the solution be spontaneously evaporated, as a colourless, shining, and transparent mass. It has no odour, and its taste is at first bitter, then pungent and acrid. It is very poisonous, dilates the pupil, has an alkaline reaction, and perfectly neutralizes acids. It resists the action of the air, easily fuses without volatilizing, and, if further heated, yields several products of decomposition containing ammonia.

Aconitine is soluble in 50 parts of hot, and in 150 parts of cold water. The hot solution yields no deposit on cooling. It dissolves in spirit of wine, and in ether. Chloride of platina does not precipitate its solutions. The atomic weight is at present unknown.

A simplification of the method of manufacturing aconitine, especially if a larger product could be obtained, would secure to the medical art a valuable remedy.—*Hdwtb. d. Chemie von Liebig u. Poggendorff.*

The Editor of the *Annals of Chymistry*, from whose journal we extract the above, adds, that he has had occasion to prepare aconitine several times, on account of the exorbitant price demanded for it (3s. per grain), and has found the use of lime far preferable to ammonia, which latter is directed in the *Ph. L.*

WE have received a number of Poggendorff's *Annalen der Physik und Chemie*, being the 9th number for 1842. Among other articles, it contains one of considerable length on the latency of light by Lewis Moser; observations on a peculiar state of iron, by C. F. Schönbein; a method of ascertaining the constants of the voltaic pile by M. H. Jacobi; and one on galvanic piles constructed with chromic acid, by the editor.

NOTE FROM DR. MARSHALL HALL.

To the Editor of the Medical Gazette.

Sir,

OBSERVING an advertisement on the cover of the last number of your journal, relative to the publication of my lectures, I think it proper to make the following statement.

The short-hand writer of the Medical Times called upon me a few days before the commencement of my lectures at St. Thomas's, to say that it was his "*intention*" to take down my lectures for that publication, adding that, as he was not versed in medical terms, it would be a service to *him* if I would correct any verbal errors in his MS. I replied that I had no objection to do so; preferring that my lectures, if published at all, should be published correctly. When I read over the notes of the first lecture, I found them, from the cause assigned, so incorrect, that it became necessary to re-write them. This too, from the same motive, I was also ready to do, time being given. But having consented to correct my lectures for correctness' sake, I did not expect that the matter would be made public, as if I had entered into a spontaneous arrangement with the editor of that publication. I beg to add that, on seeing the advertisement on the cover of your journal, I immediately addressed that gentleman, withdrawing any co-operation whatever in this matter.

I am, sir,

Your obedient servant,

MARSHALL HALL.

Manchester Square, Dec. 10, 1842.

[Bearing the same date with the preceding, the following notice appears in the "*Medical Times*,"]

"We may announce, that we commence next week giving Dr. Marshall Hall's Lectures (now in course of delivery at St. Thomas's Hospital) on the Diagnosis, Pathology, and Treatment of Diseases of the Nervous System—a set reported verbatim expressly for the Medical Times, and carefully revised by the distinguished lecturer."—*Medical Times*, Dec. 10th.

MEDICAL OFFICERS UNDER THE POOR LAW.

To the Editor of the Medical Gazette.

SIR,

A PARAGRAPH has appeared in some of the provincial papers, stating that the Poor Law Commissioners have removed from the medical officers under their control, all members of the profession who hold either Scotch degrees in medicine, or Scotch diplomas of surgery. Is this statement true? I doubt not many of your readers would like to be informed on this point. When a reply appears, I may, perhaps, communicate with you on this subject.—I remain, sir,

Your obedient servant,

E. M. R.

December 10, 1842.

[Can any of our readers inform us how the fact stands?—ED. GAZ.]

MEDICAL QUERIES.

To the Editor of the Medical Gazette.

SIR,

CAN you or any of your readers answer the following queries:—

A person dies in the provinces under suspicious circumstances, and a coroner's inquest is demanded.

1. The opinion of a member of the College of Surgeons is taken, he not being a Member of Apothecaries' Hall.

2. The opinion of a member of the Hall is taken, he not being a member of the College of Surgeons.

3. The opinion of a physician is taken, he not having the license of the London College of Physicians.

Now, in how far valid is the opinion of these three individuals, and in what instance would the verdict of the jury be vitiated, seeing that the Act says, that the coroner is to apply to a *legal* practitioner.—I am, sir,

Your obedient servant,

IATROS.

[Can any of our readers assist us in answering our correspondent?—ED. GAZ.]

LECTURES
ON THE
THEORY AND PRACTICE OF
MIDWIFERY,

*Delivered in the Theatre of St. George's
Hospital,*

By ROBERT LEE, M.D. F.R.S.

LECTURE X.

On the growth and enlargement of the uterus during pregnancy, and the structure of its coats, blood-vessels, and absorbents, at the end of the ninth month.

CESSATION of the catamenia, sense of fulness, weight or uneasiness in the region of the uterus and bladder, irritability of stomach, and of the whole nervous and vascular systems, are the most common symptoms of early pregnancy. Though the uterus, at the end of the second month, be nearly twice as large as in the unimpregnated state, its fundus cannot be felt in the hypogastrium, and, except a little fulness and softness, there is no change in the orifice and cervix. In the third month, the lips of the os uteri are thick and soft, and the finger can be introduced a little way within them, and the Nabothian glands felt enlarged. The neck of the uterus is also thicker, softer, and more elastic, than before conception. The fundus uteri can sometimes be distinctly perceived above the brim of the pelvis at the end of the third month, but more frequently it cannot before the end of the fourth. About twelve weeks from the period of impregnation, the circulation of the blood in the walls of the uterus can occasionally be heard; but the pulsations of the foetal heart are seldom perceptible before the fifth month. The body of the uterus, after the middle period of pregnancy, continues to enlarge till the end of the ninth month, while its cervix is gradually becoming shorter, and the orifice thicker and softer. The umbilicus

protrudes, and white lines are seen on the sides of the abdomen. Not only can the sound of the foetal heart, and the pulsation of the uterine blood-vessels, be distinctly heard during the latter month, but the movements of the fœtus can be felt by applying the hand over the uterus. The areolæ become broad and dark, and the glands around the nipples enlarged, and milk is often secreted.

At the end of the ninth month, if the abdominal parietes be cut open soon after death, and before the liquor amnii has escaped, the uterus is seen of a pyriform shape, like a great muscular sac half distended, occupying the whole hypogastric, umbilical, and epigastric regions. The small intestines and omentum cover its fundus, and on the sides it is surrounded by the great intestines. The peritoneum which covers the anterior surface of the uterus is in immediate contact with the peritoneum lining the abdominal muscles. The nates and head of the fœtus cause its soft plastic walls to project externally wherever they are situated within; and not unfrequently the uterus stretches out much more on one side than the other. The figure of the uterus is also modified by all the parts which surround it, especially by the spine, brim of the pelvis, and the abdominal muscles, which, pressing it before and behind, flatten the anterior and posterior surfaces. In the erect position of the body, especially if the abdominal muscles are relaxed, the fundus uteri falls forward, so that the axis of the uterus forms a great angle with the spinal column and brim of the pelvis, and approaches the horizontal line. A dull sound is emitted by the gravid uterus on percussion, and a clear sound by the intestines around it. Ovarian cysts and tumors likewise emit a dull sound: from this circumstance, and from the unequal resistance they afford to the hand, such morbid enlargements are more frequently mistaken for the gravid uterus than any other uterine tumors.

In the preceding figure from Dr. Hunter are represented the gravid uterus and its contents, and the vagina, at the beginning of the fifth month of pregnancy. The uterus is opened, shewing the decidua, through which the foetus appears in its usual attitude, with the head over the cervix. One turn of the navel-string is round the neck, and another twisted round the left ankle, and the left arm is applied over the face. The decidual cavity is not completely obliterated. The cervix is considerably shortened, and the lips thickened.

From this cast of Dr. Hunter's upon the table, and from this engraving, (see top of next page) you will form a correct idea of the size, situation, and general appearance, which the gravid uterus presents at the end of the ninth month.

These diagrams (see figs. 1, 2, and 3, next page) (from Maygrier) represent nothing but the shortening of the cervix in the progress of pregnancy. 1, is the os uteri in the early months; 2, shews the cervix uteri in the seventh month; and 3, the state of the cervix when nearly obliterated before labour commences. Dr. Montgomery's 2d figure, Plate IX., shews the state of the os uteri in the seventh month far more accurately than these figures, with the Nabothian glands developed and prominent, and a notch in the orifice from previous delivery.

The middle coat of the human gravid uterus is evidently composed of muscular fasciculi, mixed up with cellular membrane, blood-vessels, absorbents, and nerves. It is easy to demonstrate the existence of muscular fibres in the uteri of quadrupeds, and to trace them proceeding in a longitudinal direction principally from the cornua to the body of the uterus, where they become so interlaced that it is impossible to trace them any further, and shew their course satisfactorily. In the human uterus it is much more difficult to trace the course and arrangement of the muscular fasciculi, even more difficult than in the heart, and they present little else, as Dr. Hunter has observed, but irregularity and confusion. "In a woman," he says, "who died seven days after delivery, I gave up the uterus to the examination of the muscular fibres, and traced them very carefully. I stretched it gradually in warm water, then inverted it, to have a full view of its inner surface. The remains of the decidua had been melted down, and passed off with the lochia, so that the fasciculated stratum of muscular fibres appeared to be bare, and to make the internal surface of the uterus. In a great number of places, but particularly where the placenta had been fixed, the fasciculi left oval spaces between them for the passage of arteries and veins, somewhat like those separations in the tendinous fibres of the abdomen and loins, where vessels

pass out to the cellular membrane and integuments. The cervix uteri, where the penniform rugæ are situated, had not such regular nor so large fasciculi as the rest of the uterus. In the body of the uterus the fibres were very regularly circular. The fundus was made up of two concentric circular planes of fibres, at the very centre of which was the orifice of the fallopian tube. The better to conceive this arrangement of the internal muscular fibres, we may suppose each corner of the fundus uteri, where the tube is inserted, to be stretched or drawn out, so as to make two horns, or a bifid uterus, as in the quadruped; then, if we understand the inner fibres to be circular in

every part of the uterus, we understand clearly how they will be circular in the human uterus upon its body, and likewise circular and concentric at each corner of the uterus. When this internal stratum was removed, the fasciculated appearance and regular direction of the fibres was less and less apparent in proportion as I dissected outwards; which seemed, in a great measure, to be owing to the infinite number of the branches and communications of the large veins."

The uterus and its appendages are supplied with blood from the spermatic and hypogastric arteries. The spermatics, after sending branches to the tubes and ovaria, pass down

to the uterus, and there anastomose on its sides with the uterine branches of the hypogastrics. You have seen, from injected preparations, that the upper part of the uterus is chiefly supplied by the spermatic arteries, and the body, and cervix, and vagina, solely by the hypogastrics. At the full period of pregnancy all these arteries and veins of the uterus are greatly enlarged. When the arteries, which are always tortuous, reach the uterus, they do not run any distance under the peritoneum, but immediately plunge into the muscular coat, and pass toward the inner surface, and especially to the part where the placenta is attached, ramifying as they proceed. Those branches which reach the lining membrane terminate in the tortuous canals in the placental decidua. Those which do not arrive at the inner surface ramify upon the coats of the veins. The veins appear to be enlarged even in a still greater degree than the arteries. In no organ of the body does there exist such a vast collection of large veins as in the gravid uterus at the full period. If the veins could all be dissected out and put together, they would form a membranous expansion of great extent; so great that I am almost afraid to state the extent of surface which I believe they would cover. They are also, like the arteries, chiefly situated in that part of the uterus where the placenta is attached; and if the placenta be removed, you will see the veins opening into the cavity of the uterus by large oblique apertures with smooth edges. In this preparation the placenta is partially separated, and bristles have been introduced into these valvular-like venous openings in the lining membrane. These veins have no proper valves, so that if water, or any fluid, be thrown into the trunks of the hypogastric and spermatic veins, it will flow in a full stream into the cavity of the uterus. It is in this way, I conceive, and also from the exposed arteries, that such immense quantities of blood are often discharged in so short a time from the uterus during labour. In the uteri of some great quadrupeds, as the mare, the veins have valves, but not so perfect as to prevent injections passing from their trunks to their branches. If you trace the veins in the human uterus from these smooth openings in the lining membrane, you will see them entering obliquely into one another, and increasing in size as they reach the surface and sides of the uterus. I have filled the whole venous system of the uterus by tying the trunks of the spermatic and hypogastric veins, and pouring injection into the cavity of the uterus. In this gravid uterus at the full period, the aorta and its branches, and the vena cava and the iliac veins in the muscular coat, are filled with injection, and you can

see how very large the veins are in the wall of the uterus to which the placenta is attached. From this preparation you will easily perceive how readily the venous circulation in the uterus and placenta may be interrupted by all the different derangements of function in the thoracic and abdominal viscera, and how important it must be to obviate all obstructions in these during pregnancy.

Dr. Hunter states that Mr. Cruikshank was the first who observed at the Anatomical School of Great Windmill Street, the lymphatics in the gravid uterus, and that he injected them with great success in several subjects. "They are more numerous," he adds, "and many of them larger than could be imagined: from which it is manifest that a copious absorption is carried on in the uterus towards the mother. The lymphatics pervade its substance universally: its peritoneal coat appears like that of a calf's spleen, to be interwoven with a crowded plexus of these vessels; and where they get to the sides of the uterus, when filled with mercury, some of them are even larger than a goose-quill. Some are remarkably varicose, or enlarged at particular places. They pass from the sides of the uterus, many with the spermatic vessels, but the greater number and the larger with the hypogastrics. Of these last, some pass into glands on the side of the vagina, others meet with no glands till they have reached the side of the pelvis, when they run into the glands of the iliac plexus; from both of which they pass into the lumbar plexus, where they are lost among the absorbents of the lower extremities, and the external parts of generation. Besides the lymphatic vessels of the uterus, there are others, as we hinted above, belonging to the ovaria and fallopian tubes, which follow the course of the spermatic arteries and veins. They anastomose with the lymphatics of the uterus, and terminate in glands which are placed upon the sides of the lumbar vertebræ, near the origin of these blood-vessels: here they become mixed with the lymphatics of the lumbar plexus, and enter with them into the lower end of the thoracic duct. The spermatic lymphatics enlarge during pregnancy, in the same manner as the blood-vessels: and for this reason they are both readily seen and injected. The reason why the blood-vessels, lymphatics, and nerves of the ovaria, and the fallopian tubes, have their origin in the loins, is the same with that of the origin of similar vessels and nerves in the male; they are not placed in the cavity of the pelvis in the early foetal state, but upon the *psosæ* muscles, some little way under the kidneys. It is natural, therefore, that these vessels and nerves should arise near the vessels and nerves of these organs." It is here said that the absorbents

pervade the substance of the uterus universally, but their course and structure are not described, and it is not stated that they were traced to the inner surface, and that they had valves. When at Glasgow some years ago, I neglected to enquire about these preparations made by Mr. Cruikshank, whether they had been preserved in the Museum. If they had, I think Dr. Burns would have described the absorbents of the uterus more minutely than he has done. He says merely, that they are large and numerous. Having sacrificed all the gravid uteri which I have met with to nerves, and blood-vessels, and other structures, I regret extremely that I have no preparation to demonstrate the absorbents of the human gravid uterus, and I have never seen a preparation in which they were injected. There were some, I am informed, in the collection of Sir Charles Bell, which went to Edinburgh, but I have no recollection of them. I have often traced absorbents with the spermatic vessels to the uterus, and also with the hypogastric, but never into the substance of the uterus to any distance, and I do not know any thing of their course except from what I have seen in cases of uterine inflammation after delivery, where they were distended with pus, and where they appeared to accompany the veins; had a beaded appearance, with numerous valves, and their coats were thin and transparent. They are seen distended with pus in this drawing, and in these coloured plates of Cruveilhier and Carswell. There are two views of the healthy absorbents of the uterus in Mascagni's plates, and also in M. Moreau's work, which I now shew you.

Malpighi describes the absorbents of the uterus in some quadrupeds, and he says they form a great system of vessels. In this gravid uterus of the mare, [placed before you] they have been very successfully injected with blue size, and their course traced from the horns of the uterus down to the cervix accompanying the trunks of the uterine branches of the hypogastric veins. You will see that the trunks of the absorbents chiefly follow the veins, and that they are provided with numerous valves, which are so perfect that neither air, mercury, nor size, can be made to pass into them in the retrograde direction. I introduced first a small blow-pipe into one of the branches in the right horn, and the air ran forward and filled the whole vessel, which was perfectly transparent to the neck of the uterus. Having succeeded in filling them with air, I did so with mercury, and it also flowed forward, but it was too heavy, and soon burst through their delicate coats. Size being much lighter, after allowing all the mercury to escape, it was thrown in, and has been retained, and all the absorbents, at least all the principal branches, are filled with blue size,

and present a very beautiful appearance. Small arteries injected with vermilion, and even filaments of nerves, are distinctly seen ramifying upon the coats of the absorbents. (Several inches of one of the absorbent trunks have been cut out and suspended in spirit to shew this, and it forms an interesting preparation) [exhibiting it.] I thought this was the first time the arteries of the coats of the uterine absorbents had been seen, but I was mistaken, for Cruikshank describes the arteries of these vessels. I believe, however, this is the first time filaments of nerves have been seen on the coats of the absorbents, which proves that they have nervi and vasa vasorum, like blood-vessels. Under the peritoneum of the left horn of this uterus, you can see numerous small absorbent vessels entering a sac about the size of a large pin's-head: from this sac you can see three absorbent vessels passing out, which have also been filled with blue injection, and which run forward about half an inch, and enter another oblong sac about twice the size of the first. Numerous minute absorbents enter this second sac, which is much thicker than any of the absorbents entering it, or indeed than the trunk of the absorbents near the neck of the uterus. From the second lymphatic sac a large absorbent vessel passes out, which proceeds down to the body of the uterus, receiving numerous other branches, and gradually enlarging till it attains the size of a small goose-quill. I suspect that these lymphatic sacs are analogous to those which exist in reptiles, which are called lymphatic hearts, and that they collect and propel the fluid along the absorbents.

If the absorbents of the human uterus are equally developed during gestation, and Dr. Hunter's description of them makes it certain that they are so, it is obvious that they are intended to perform another function besides that of carrying on "a copious absorption in the uterus towards the mother during pregnancy." The sudden removal of the uterine structures after delivery by absorption is probably the most important office they perform, and the cause of their enlargement to such a vast size during the latter months of pregnancy.

REMOVAL OF A DROPSICAL OVARIUM, ENTIRE,

BY THE LARGE ABDOMINAL SECTION.

BY D. HENRY WALNE, ESQ.

(For the London Medical Gazette.)

It is now about twenty years since that able physiologist and discriminating physician, Dr. James Blundell, in

calling the attention of surgeons to a series of facts and experiments calculated to illustrate its truth, made this observation:—"Of all the branches of surgery, there is none, I conceive, which in this country admits of greater improvement than the surgery of the abdomen;" and in prosecuting his comprehensive view of the subject, among other suggestions, foreign to my present purpose, he advanced the opinion that "extirpation of the ovarian cyst in scirrhus combined with dropsy, or in simple dropsy," would, as an operation, "ultimately come into general use." He was enabled, indeed, to refer to two cases only, in which an operation had been performed, coming so immediately under his notice as to justify citation, one of which was successful, and one otherwise.

Of these two cases, one certainly, that of Dr. Nathan Smith, was treated by what may now be best distinguished by the term minor operation,* the incision into the abdomen, as we learn from another source, being of three inches extent only, and reduction of the bulk of the tumour having been effected by tapping the cyst, and withdrawing eight pints of fluid before extraction of the sac itself. It is worthy of remark that adhesion of the cyst to the omentum existed in this instance, and was divided by the knife, yet the patient recovered.

It does not appear quite clearly, by Dr. Blundell's short account of the other case, (given with other objects than its description), what exact steps constituted the operation, but I infer that a more extensive incision was practised, from the circumstance of the sac being "drawn forth before it was cut into:" yet it could not have been performed by the full-sized abdominal section, to which the name of major operation justly applies†.

* To readers who have only slightly or never before given any attention to this subject, it may be desirable to remark that two forms of operation have been proposed for the cure of ovarian encysted dropsical disease, chiefly distinguished by the circumstance of the one being practised by a small, the other by a free large incision into the abdomen. Hence the terms major and minor operation, which are found convenient in speaking of them. In the one the bulk of the disease must be reduced before extraction; in the other it is, if possible, removed entire.

† Since writing the above remark, Dr. Blundell has informed me that the section was of the extent of three inches and a half. "The ovary was first tapped, then drawn out, and in the third place cut into, and away."

Not long after the publication of Dr. Blundell's *Physiological Researches*, which were the substance of papers read to the *Medico-Chirurgical Society* several years previously, some accounts fell into the hands of Mr. Lizars, of Edinburgh, of so surprising a character, and at the same time so very imperfect, that they did not gain immediate or general credence; but which have since been admitted to be unquestionably true. By these it was shewn that Dr. M'Dowal, of Danville, in Kentucky, had, as early as 1809, successfully performed one operation for extirpation of a diseased ovary, practising an extensive incision into the abdomen; and between that period, and May 1816, two other nearly similar operations. Mr. Lizars not only published these accounts, but having himself made a succession of trials, of a bold and enterprising character, directed to the same great object which had occupied the mind of Dr. Blundell, and the adventurous spirit of Dr. M'Dowal and Dr. Nathan Smith—viz. the cure of an otherwise hopeless disease—had the manly candour, and moral courage, equalling his surgical intrepidity, to give to the professional world a full narrative of his unsuccessful attempts; coupled, however, with one triumphant case of the major operation, in which, through an opening of twelve inches into the abdominal cavity, he had succeeded in removing a large diseased ovary, complicated with ascites to the extent of a gallon and a half of serous fluid. His patient so completely recovered that she paid a visit to London by the invitation of Dr. Blundell, and the most incredulous were convinced of the practicability, at least, of this form of operation. Still, however, an extraordinary apathy on the subject continued to affect the whole profession in Great Britain, and I am not aware that this operation has ever, till within these few months, been repeated by a British surgeon; and I believe that it never had been performed at all in England, before Dr. Charles Clay, of Manchester, on the 12th of September last, operated in his first case, nor in London, until, on November 6th, I operated in the case I am about to record. The minor operation had, indeed, been performed in different parts of the country by several gentlemen, with various success, but it is clearly shewn

to be inapplicable to a large proportion of the examples of the disease which come under treatment.

Between four and five months ago a case of ovarian disease presented itself which I thought might be treated by operation, with a reasonable prospect of success, as it held out the probability of freedom from adhesion, and did not appear to be of a very solid character. An accidental disturbance of the health of my patient, and the period required for her comfortable restoration by a visit to the country, had served to postpone my purpose, so that by the time at which I had proposed to operate, Dr. C. Clay's first case was published; and this served to decide my choice of operation. I determined to extirpate the diseased ovary by the large abdominal section, and found a ready approval of my purpose on the part of Dr. Blundell, whose careful investigation of the case had already confirmed my own opinion of its nature.

Accordingly I arranged for the performance of the operation on the 6th of November, but had the still farther satisfaction of seeing Dr. Clay's second successful case in print on the 5th, and of receiving the same day an obliging answer to two or three inquiries as to minor details of the operation, which, though a stranger to him, I had not hesitated to make.

My reasons for preferring to operate by the larger section were these: that it does not appear that a less extent of wound diminishes the danger of the operation in any material degree, if at all; and that the complications which occasionally present without being foreseen, and which, indeed, do not admit of being foreseen in every instance, can be better appreciated, and more suitably dealt with by the surgeon, through a free opening than through a small one.

For example, the effusion of blood, or the escape of fluid from the cyst into the peritoneum, either of which is a most dangerous complication of the difficulties inseparable from any method of operating, can with no certainty be avoided in the minor, but may assuredly be remedied if they should occur in the major operation. Adhesions, too, can be divided, the parts can be cleansed and arteries tied with facility, if necessary, and the operator's mind freed from doubt as to the state of the internal parts, before he carefully

closes the wound. These are circumstances which the experienced operator can appreciate, and if he should not be blinded by an undue apprehension of peritoneal inflammation, he will be sure to estimate highly such palpable advantages.

To proceed with the case:—

Mrs. F——, of — Street, Marylebone, æt. 58, applied to me some time in the month of July with great abdominal enlargement, equalling indeed that of pregnancy at the full period. The catamenia had ceased four years. She used to be subject to floodings. Had given birth to five living children, and miscarried several times. A rounded prominence of the abdomen, of a circumscribed character, with fluctuation, and moveable as a whole, was found on examination; whilst the health was good, and there was no sign of general dropsy present. She had observed her gradual increase of size for more than two years, and, as she could not account for it, had lately felt uneasy on the subject, though it caused her no pain, and was, indeed, only an encumbrance, and made her unpleasantly remarkable. From scrob. cordis to pubes was $17\frac{1}{2}$ inches; her circumference was $37\frac{1}{2}$ inches. I pronounced her case, on investigation, one of ovarian disease, and after a few interviews, referred her for confirmation of my opinion to Dr. Blundell. Having obtained this, I began to hint at the means of cure, and having gradually gained her confidence more and more, and as gradually intimated my purpose; not concealing from her or her family the risk attending the measure; after the cause of postponement above alluded to had been removed, fixed the day of operation, with her ready and full concurrence, and enlisted my friendly coadjutors for the occasion. A few hours before the time appointed, I went over the steps of the operation with a part of these friends; to one of whom was assigned the charge of the tumour, exclusive of all other engagements; to another, that of covering the exposed interior parts by the divided skin, the moment opportunity should offer. The temperature of the room was to be raised rather above 70° Fah.; and means were adopted to secure it from change in this respect as much as possible. A mild dose of aperient medicine, given over night, not having

acted, an enema, administered half an hour before the time named, gave the required relief.

Dr. Blundell, Mr. Vincent, Mr. L. Beale, Mr. Law, and Dr. Freund, of Vienna, were punctual, and between 3 and 4 o'clock, P.M., the patient was placed upon a couch, with her feet upon the ground at its end, and her back supported by pillows. Some little preliminary examination having been made, and myself and more fixed assistants having taken our posts, myself seated on her right, for the satisfaction of all parties I commenced with an exploratory incision of the integuments and tendinous expansion, and then of the peritoneum, to the extent of an inch and a half. A finger was passed on each side into the peritoneal cavity, and the fluctuating cyst distinguished quite clearly. No fluid escaped. I now proceeded with the scalpel to enlarge the incision from above downwards, including that already made, to the length of thirteen inches, or a little more, first in the integuments, avoiding the umbilicus, and afterwards in the peritoneum, from the small opening, with a probe-pointed bistoury, guided by two fingers of my left hand, upwards and then downwards to the same extent, being from about three inches below the scrobiculus cordis to within one and a half of the pubes. This accomplished, the wound began to expand on each side, and the tumour to advance gently, but more briskly when its greatest bulge had passed through the wound; demonstrating the propriety of some one being appointed for its management, and giving the most satisfactory evidence of its being mainly free from unnatural attachment. It had not been ascertained with certainty which ovary was affected, but the right was suspected to be the one, and so it proved. I now passed two fingers behind the broad ligament, and Mr. Law sustained the tumour, which might otherwise have fallen forwards. With a needle, having its eye near the point, and fixed in a handle, guided by the two fingers, I passed a double ligature behind the pedicle, and thrusting the needle through the middle of that part, brought its point forward. The ligature was divided, and disentangled from the needle, which was then withdrawn. The tails of the ligature being adjusted for

tying the two halves of the pedicle separately, I now tied one of them, but in doing so the silk broke. The remaining one was used for introducing a second double ligature, with which the former had to be replaced. After tying the pedicle, I divided it between the tumour and the part tied, and, having done so, had the satisfaction to see the huge mass of more than 16 lbs. weight lifted from its place, and carried away by Mr. Law, no adhesions whatever interfering. I now examined the cut end of the pedicle, and tied a considerable artery. At this period the patient became very sick, and made repeated efforts to vomit, but nothing was brought up. Dr. Freund had been in charge of the divided integuments, and closed them over the abdominal viscera, securing the intestines from exposure to air as much as possible. Whilst the retching efforts continued I aided him in this work, and my other friends were taking every care of the patient in other respects. When these had ceased I again looked for bleeding vessels; but as there was a general oozing, rather than any other form of bleeding, it was agreed to tie the pedicle in its entire circumference, some notion prevailing that the needle might have severed a vessel at a distance from the cut surface. I accordingly did this with double staysilk. Bleeding ceased, the wound was cleansed, the other ovary examined by Dr. Blundell, and nothing remained to be done but to close and stitch the wound. About a dozen of interrupted sutures through the integuments, which had been marked before the operation for our guidance at this moment, served to bring the parts together. Long pads of lint were laid down each side of the abdomen a little away from the wound, and strips of a mild adhesive plaster carried over them from one side of the body to the other. A broad bandage, entire at the middle, but slit up into eight roller-heads, and previously laid ready beneath her back, was made comfortably tight, and the ends, after once encircling her, tied on alternate sides of the patient's abdomen. This seemed to give her a satisfactory feeling of security, and drew from her a remark of approval.

At the conclusion of the operation, her pulse was 76, counted by Dr. Blundell: it had been exactly that number

when reckoned by myself the evening before: she was, however, pale and cold, and when laid in bed requested to have something given to quiet her nerves: a bottle of hot water was put to her feet, she was well covered up, and an anodyne administered, with directions to repeat it in an hour: it was composed of $\frac{1}{4}$ gr. Morph. Acetat. and $\frac{3}{4}$ ss. Mist. Camph.; and was so repeated. At 5 o'clock, her pulse was 82. When I visited her at 8, it was 96. She had become warm after the anodyne, and having slept two hours, was now perspiring freely. From this time she was neither cold nor had chilly sensation: on waking from her sound sleep, she was at first a little confused, but this soon ceased, and she was generally quite clear and calm in mind. When the pedicle was tied the first time, she had complained of some pain in the loins, and still more at the second tying of that part; a general smarting of the wound was also, of course, felt. These continued between two and three hours, but had now subsided almost entirely. A sensation of throbbing succeeded, which also ceased in the course of the night. At 12 o'clock, I paid her my final visit, and drew off five ounces of urine. She had slept three hours since 8 o'clock: pulse 94 before, 89 after the use of the catheter. No unfavourable symptoms.

Nov. 7th.—I visited her at 9 A.M., 4, and 11 P.M., and each time used the catheter, withdrawing in all $14\frac{1}{2}$ ounces of urine. The pulse at each visit respectively 90, 96, 86 when asleep, 90 after awaking. Having passed a comfortable night, at least sleeping great part of the time, she also slept a good deal in the day; was free from pain, had no abdominal tenderness, except in the line of the wound, and no distension, flatulency, or sickness; she perspired freely, and was comfortably warm. Had taken nothing but toast-water, and as too little of this even had been given, in the great caution used to avoid distension from any cause, was rather thirsty in the afternoon, but when more was allowed complained towards night that it did not quite suit her stomach. Mint-tea was then proposed, but not taken. A spoonful or two of panada in the evening was the only thing taken besides, until at night her anodyne of $\frac{1}{4}$ gr. Acetate of Morphine and $\frac{3}{4}$ ss. Mist. Camph., was

repeated, which relieved the slight uneasiness of the stomach. The total abstinence observed throughout the day was in accordance with her own feeling as well as my wish, as "she often ate nothing for two days or more when her stomach was out of sorts."

8th.—The second night was not equally good; indeed, she had been somewhat hot and restless, but still perspiring. The thirst continued, and sickness had twice or thrice occurred in the night. Small quantities of soda-water, not in its full activity, were now allowed, and she took a bottle and a half in the course of the day. I visited her four times, and the pulse was noted at each of the visits twice, the catheter, except at mid-day, being used between making the first and second note.

3iv. of urine only withdrawn in the morning. I was induced by this circumstance to omit the use of the catheter at 2 o'clock. In the evening I received two messages, and at 9 o'clock found her very uneasy, with a strong desire to pass urine and stool, but afraid to make any effort. The catheter and an enema of warm water afforded great relief. Flatus passed from the bowels, and 3vi. of urine were withdrawn. Vomiting and occasional eructation of wind had occurred. She had changed her posture in bed several times, and was not easily restrained from making imprudent sudden movements in her state of uneasiness. During my 9 o'clock visit this was very much the case, and after one of her movements of this kind she became alarmed by feeling something hot on the skin of the abdomen. On examination I found serum trickling down the skin from the wound. I afterwards suspected that the ligatures which had been left out about two inches from the pubic end of the wound must have been pulled a little way within it at this juncture, as the ends were not visible when I made my first dressing. Being very much relieved by what had been done for her, and the anodyne having been repeated, at half after 12 o'clock I found that three hours of comfortable sleep, and a subsidence of twelve beats in the frequency of the pulse, had been the

happy consequences of the measures. Her mind was clear, and her skin moist all day, but after the anodyne warm and perspiring freely, the tongue moist; but vomiting always disguises the state of the tongue in that respect, so as to render it almost useless as a criterion of the patient's condition.

9th.—Hours of visiting and state of pulse.

	10 A.M.	4 P.M.	11 P.M.
1st trial	100	100

She slept two-thirds of the night, and passed, unaided, ζ ix. of urine before my first visit, and ζ vss. after it. Felt a wish for food, and took panada. The sickness had ceased. She slept in the day, and again took a little simple food at night. It was panada, or something sopped, as biscuit, I believe. Complained of slight pain at the pit of the stomach. The enema and the anodyne were repeated. Her tongue was moist and cleaner, and the skin perspiring.

10th.—Had two motions from the enema last night, and passed ζ ix. of urine at twice. Had been somewhat restless and moving; was thirsty, and had occasional sickness. Took a cup of tea and a little biscuit for breakfast. Skin moist; tongue moist and brown; some griping pain; passed ζ xii. more urine in the course of the day. The temperature of the room, which had been preserved almost uniformly at 70° , or a trifle above that degree, and only once before lowered to 67° for a few hours, was now reduced to 66° . All this day the pulse ranged from 80 to 82, a fall attributable to the free relief of the bowels the previous night, yet some uneasiness of a griping kind was now and then felt. Enema repeated; anodyne conditionally ordered, but not taken.

11th.—She had not had so good a night; vomiting had twice occurred, with strong retching, and she had brought up a good deal of bile: there was constant nausea, and occasional eructation; ζ vj. of urine; no motion; occasional griping; pulse 80. I dressed the wound, removing all the stitches below the umbilicus, but leaving those above that part. I directed that some beef-tea should be given with salt in it.

At mid-day the symptoms were not amended. Pulse 83; tongue dark-

brown, and much coated; her manner drowsy, and her mind at times confused; constant nausea, occasional vomiting, and frequent hiccup, with pain at the navel. These symptoms made me anxious for her safety. They were those of intestinal distress, and reminded me of such as occur in strangulated hernia, and at the ushering in of intestinal fever of a bad form. I speculated on the circumstance of the disappearance of the ligatures, and how they might contribute to the production of the symptoms. I deemed it useless to search for them, as their attachment to the pedicle would render their removal, if found, impracticable; and after conferring with my friends Dr. Blundell and Mr. Vincent, determined to make no attempt of that kind, but give the anodyne, then an enema in two hours, and repeat the anodyne if necessary. All this was done. The first anodyne relieved the sickness, procured her some better sleep, and revived her very much. The enema produced a discharge of flatus and some little feculent matter. She had a tranquil night after the second anodyne, and on the morning of the 12th felt better; having passed ζ xi. of urine in the night, and having been scarcely at all sick. Pulse 79, soft and full; skin warm, and freely perspiring; occasional hiccup, which still causes pain at the navel. Wished for tea and toast, and took some beef-tea with toast in it.

Throughout the day she continued to improve. She passed ζ ix. more urine. At night the enema, and then the anodyne, were repeated: the former produced a motion, which, in part, consisted of a large hard lump of feces; her night was good, and on the

13th.—She had neither pain nor sickness. ζ xvj. of urine passed in as many hours; her tongue was moist, and rapidly cleaning, yet the singultus occasionally returned: this, she said, she was very apt to experience when well, and was partially relieved by sipping water. I dressed the wound, removing the remaining stitches: adhesive matter was covering those parts of it which were not closed, and which, at three points together, amounted to less than three inches. She was cheerful and comfortable at noon, when the wound was dressed, but within a very little time had again some nausea and other symptoms resembling those of

incarcerated hernia. She thought the dressings too tight, and, on raising one end of the strips of plaister, it was found that one of them in particular had been so; it lay over a part of the wound not yet quite closed, where intestine, slightly protected by adhesive matter, was liable to pressure. On my removing this piece of plaister she felt sickish and faint, but immediately after much relieved: it had evidently contributed to the renewal of unpleasant symptoms; and the circumstance is, I think, one of great practical interest, for it confirms the observation which the whole circumstances of the case, after the completion of the operation, are calculated to draw forth, viz., that it is not so much peritoneal inflammation as suffering in the viscera of the abdomen, more particularly the intestines, which is to be apprehended as a consequence of free incision for the removal of diseased ovarium.

Having obtained great relief from the loosening and more lightly adjusting the dressings of the wound, one other cause of uneasiness and anxiety remained. Several hours had elapsed without her having passed her urine, and she felt doubtful of her power to do so: the catheter was accordingly used for the last time. The enema and the anodyne were also repeated.

14th.—She had slept well, and at 5 in the morning voided her urine naturally. No sickness had occurred; her tongue was clean and moist; pulse 78 and soft; passed six. of urine in the day, and, except a slight degree of light-headed feeling, and a rather violent fit of hiccough in the evening, was comfortable throughout this day, and had taken beef-tea, arrow-root, &c., more freely.

R. Fel. Bov. gr. x. h. s. s.

15th.—Passed a tranquil night without the anodyne, and feels quite well; singultus less troublesome; wished for leave to sit up, but felt weak and languid. Ordered a little port wine.

16th.—Better in all respects; relished some chicken.

From this time she continued to improve daily. On the 20th, said she felt as if she could stand and walk, but still had some uncomfortable feeling, and slight difficulty in passing her urine. The hiccough did not entirely cease till about this time, though it was
